Biochemistry, Seventh Edition
Reginald H. Garrett, Charles M. Grisham

SVP, Higher Education Product Management:
Erin Joyner

VP, Product Management, Learning
Experiences: Thais Alencar

Product Director: Maureen McLaughlin

Product Manager: Roxanne Wang

Product Assistant: Ellie Purgavie

Developmental Editor: Maria Lokshin

Learning Designer: Mona Zeftel

In-House Subject Matter Expert: Dakin Sharum

Senior Content Manager: Meaghan Ford

Digital Project Manager: Nikkita Kendrick

Content Program Manager: Ivan Corriher

Senior Content Quality Assurance Engineer:
Lalitha Balusu

VP, Product Marketing: Jason Sakos

Senior Director, Product Marketing:
Danaë April

Product Marketing Manager: Andrew Stock

Cover Design: Chris Doughman

IP Analyst: Ann Hoffman

Senior IP Project Manager: Betsy Hathaway

Production Service: Lumina Datamatics, Ltd.

Cover Image: CRISPR-Cas9, by Tina Chai

Cengage is a leading provider of customized learning solutions with employees residing in nearly 40 different countries and sales in more than 125 countries around the world. Find your local representative at: **www.cengage.com**.

To learn more about Cengage platforms and services, register or access your online learning solution, or purchase materials for your course, visit **www.cengage.com**.

Dedication

To our grandchildren Jackson, Bella, Reggie, Ricky, Charlotte Mayberry, Ann Clara, and Kathleen Elizabeth, and to the generations to follow...

About the Authors

Reginald H. Garrett was educated in the Baltimore city public schools and at the Johns Hopkins University, where he earned his Ph.D. in biology in 1968. Since then, he has been at the University of Virginia, where he is a Professor Emeritus of Biology. He is the author of previous editions of *Biochemistry* as well as *Principles of Biochemistry* (Cengage, Brooks/Cole) and numerous papers and review articles on the biochemical, genetic, and molecular biological aspects of inorganic nitrogen metabolism. His research interests focused on the pathway of nitrate assimilation in filamentous fungi. His investigations contributed substantially to our understanding of the enzymology, genetics, and regulation of this major pathway of biological nitrogen acquisition. More recently, he has collaborated in systems approaches to the metabolic basis of nutrition-related diseases. His research has been supported by the National Institutes of Health, the National Science Foundation, and private industry. He is a former Fulbright Scholar at the Universität für Bodenkultur in Vienna, Austria and served as Visiting Scholar at the University of Cambridge on two separate occasions. During the second, he was the Thomas Jefferson Visiting Fellow in Downing College. In 2003, he was Professeur Invité at the Université Paul Sabatier/Toulouse III and the Centre National de la Recherche Scientifique, Institute for Pharmacology and Structural Biology in France. He taught biochemistry at the University of Virginia for 46 years. He is a member of the American Society for Biochemistry and Molecular Biology.

Charles M. Grisham was born and raised in Minneapolis, Minnesota, and educated at Benilde High School. He received his B.S. in chemistry from the Illinois Institute of Technology in 1969 and his Ph.D. in chemistry from the University of Minnesota in 1973. Following a postdoctoral appointment at the Institute for Cancer Research in Philadelphia, he joined the faculty of the University of Virginia, where he is Professor of Chemistry. He is the author of previous editions of *Biochemistry* and *Principles of Biochemistry* (Cengage, Brooks/Cole) and numerous papers and review articles on active transport of sodium, potassium, and calcium in mammalian systems, on protein kinase C, and on the applications of NMR and EPR spectroscopy to the study of biological systems. He also authored *Interactive Biochemistry CD-ROM and Workbook*, a tutorial CD for students. His work has been supported by the National Institutes of Health, the National Science Foundation, the Muscular Dystrophy Association of America, the Research Corporation, the American Heart Association, and the American Chemical Society. He is a Research Career Development Awardee of the National Institutes of Health, and in 1983 and 1984 he was a Visiting Scientist at the Aarhus University Institute of Physiology Denmark. In 1999, he was Knapp Professor of Chemistry at the University of San Diego. He has taught biochemistry, introductory chemistry, and physical chemistry at the University of Virginia for 48 years. He is a member of the American Society for Biochemistry and Molecular Biology.

Reginald H. Garrett and Charles M. Grisham

Gene Runion

Contents in Brief

Part I Molecular Components of Cells 1

- 1 The Facts of Life: Chemistry Is the Logic of Biological Phenomena 1
- 2 Water: The Medium of Life 29
- 3 Thermodynamics of Biological Systems 51
- 4 Amino Acids and the Peptide Bond 77
- 5 Proteins: Their Primary Structure and Biological Functions 105
- 6 Proteins: Secondary, Tertiary, and Quaternary Structure 145
- 7 Carbohydrates and the Glycoconjugates of Cell Surfaces 193
- 8 Lipids 237
- 9 Membranes and Membrane Transport 265
- 10 Nucleotides and Nucleic Acids 317
- 11 Structure of Nucleic Acids 345
- 12 Recombinant DNA, Cloning, Gene Editing, and Synthetic Biology—An Introduction 393

Part II Protein Dynamics 433

- 13 Enzymes—Kinetics and Specificity 433
- 14 Mechanisms of Enzyme Action 475
- 15 Enzyme Regulation 511
- 16 Molecular Motors 543

Part III Metabolism and Its Regulation 573

- 17 Metabolism: An Overview 573
- 18 Glycolysis 603
- 19 The Tricarboxylic Acid Cycle 635
- 20 Electron Transport and Oxidative Phosphorylation 671
- 21 Photosynthesis 713
- 22 Gluconeogenesis, Glycogen Metabolism, and the Pentose Phosphate Pathway 751
- 23 Fatty Acid Catabolism 791
- 24 Lipid Biosynthesis 821
- 25 Nitrogen Acquisition and Amino Acid Metabolism 871
- 26 Synthesis and Degradation of Nucleotides 921
- 27 Metabolic Integration and Organ Specialization 951

Part IV Information Transfer 981

- 28 DNA Metabolism: Replication, Recombination, and Repair 981
- 29 Transcription and the Regulation of Gene Expression 1033
- 30 Protein Synthesis 1089
- 31 Completing the Protein Life Cycle: Folding, Processing, and Degradation 1131
- 32 The Reception and Transmission of Extracellular Information 1161

Abbreviated Answers to Problems A-1

Index I-1

Detailed Contents

Part I Molecular Components of Cells 1

1

The Facts of Life: Chemistry Is the Logic of Biological Phenomena 1

- 1.1 What Are the Distinctive Properties of Living Systems? 1
- 1.2 What Kinds of Molecules Are Biomolecules? 4
 - Biomolecules Are Carbon Compounds 5
- 1.3 What Is the Structural Organization of Complex Biomolecules? 5
 - Metabolites Are Used to Form the Building Blocks of Macromolecules 5
 - Organelles Represent a Higher Order in Biomolecular Organization 8
 - Membranes Are Supramolecular Assemblies That Define the Boundaries of Cells 9
 - The Unit of Life Is the Cell 9
- 1.4 How Do the Properties of Biomolecules Reflect Their Fitness to the Living Condition? 10
 - Biological Macromolecules and Their Building Blocks Have a “Sense” or Directionality 10
 - Biological Macromolecules Are Informational 11
 - Biomolecules Have Characteristic Three-Dimensional Architecture 12
 - Weak Forces Maintain Biological Structure and Determine Biomolecular Interactions 12
 - Van der Waals Forces Are Short-Range Interactions between Atoms in Nearby Molecules 12
 - Hydrogen Bonds Form between H Atoms and Electronegative Atoms Like N and O 14
 - Ionic Interactions Form between Oppositely Charged Groups or Molecules 14
 - Hydrophobic Interactions Are the Result of Favorable Interactions between Water Molecules 14
 - The Defining Concept of Biochemistry Is “Molecular Recognition through Structural Complementarity” 14
 - Biomolecular Recognition Is Mediated by Weak Chemical Forces 15

Weak Forces Restrict Organisms to a Narrow Range of Environmental Conditions 16

Enzymes Catalyze Metabolic Reactions 17

Biomolecular Phenomena across the Time Scale of Life 17

1.5 What Are the Organization and Structure of Cells? 17

The Eukaryotic Cell Likely Emerged from an Archaeal Lineage 18

How Many Genes Does a Cell Need? 18

Critical Developments in Biochemistry: Synthetic Life 19

Archaea and Bacteria Have a Relatively Simple Structural Organization 20

The Structural Organization of Eukaryotic Cells Is More Complex Than That of Prokaryotic Cells 21

1.6 What Are Viruses? 22

Foundational Biochemistry 25

Problems 25

Further Reading 27

2

Water: The Medium of Life 29

2.1 What Are the Properties of Water? 29

Water Has Unusual Properties 30

Hydrogen Bonding in Water Is Key to Its Properties 30

The Structure of Ice Is Based on H-Bond Formation 30

Molecular Interactions in Liquid Water Are Based on H Bonds 31

The Solvent Properties of Water Derive from Its Polar Nature 32

Water Can Ionize to Form H^+ and OH^- 36

2.2 What Is pH? 37

Strong Electrolytes Dissociate Completely in Water 38

Weak Electrolytes Are Substances That Dissociate Only Slightly in Water 39

The Henderson–Hasselbalch Equation Describes the Dissociation of a Weak Acid in the Presence of Its Conjugate Base 39

Titration Curves Illustrate the Progressive
Dissociation of a Weak Acid 41

Phosphoric Acid Has Three Dissociable H^+ 42

2.3 What Are Buffers, and What Do They Do? 43

The Phosphate Buffer System Is a Major Intracellular
Buffering System 43

The Imidazole Group of Histidine Also Serves
as an Intracellular Buffering System 44

The Bicarbonate Buffer System of Blood Plasma 44

Buffers Useful within Physiological pH Ranges 45

Human Biochemistry: Blood pH and Respiration 46

2.4 What Properties of Water Give It a Unique Role in the Environment? 46

Foundational Biochemistry 47

Problems 47

Further Reading 49

3

Thermodynamics of Biological Systems 51

3.1 What Are the Basic Concepts of Thermodynamics? 51

Three Quantities Describe the Energetics
of Biochemical Reactions 52

All Reactions and Processes Follow
the Laws of Thermodynamics 53

**A Deeper Look: Entropy, Information, and the
Importance of “Negentropy” 54**

Free Energy Provides a Simple Criterion for Equilibrium 54

3.2 What Is the Effect of Concentration on Net Free Energy Changes? 55

3.3 How May Standard State, Equilibrium, and Cellular Conditions Be Compared? 56

3.4 What Are the Characteristics of High-Energy Biomolecules? 57

High Energy Phosphate Compounds 58

A Deeper Look: Why Nature Chose Phosphates 59

ATP Is an Intermediate Energy-Shuttle Molecule 59

The Hydrolysis of Phosphoric Acid Anhydrides
Is Highly Favorable 60

The Hydrolysis ΔG° of ATP and ADP Is Greater Than
That of AMP 61

Acetyl Phosphate and 1,3-Bisphosphoglycerate
Are Phosphoric-Carboxylic Anhydrides 61

Enol Phosphates Are Potent Phosphorylating Agents 62

The Complex Equilibria Involved in ATP Hydrolysis 64

3.5 How Do Group Transfer Potentials Quantify the Reactivity of Functional Groups? 65

3.6 What Are Reduction Potentials, and How Are They Used to Account for Free Energy Changes in Redox Reactions? 66

Standard Reduction Potentials Are Measured
in Reaction Half-Cells 66

$\mathcal{E}_o'$ Values Can Be Used to Predict the Direction
of Redox Reactions 67

$\mathcal{E}_o'$ Values Can Be Used to Analyze Energy Changes
in Redox Reactions 67

The Reduction Potential Depends on Concentration 69

3.7 Why Are Coupled Processes Important to Living Things? 69

**A Deeper Look: Coupling a Reaction to ATP Hydrolysis
Changes Its K_{eq} by a Factor of 10^8 71**

3.8 What Is the Daily Human Requirement for ATP? 71

Foundational Biochemistry 72

Problems 73

Further Reading 75

4

Amino Acids and the Peptide Bond 77

4.1 What Are the Structures and Properties of Amino Acids? 77

Typical Amino Acids Contain a Central Tetrahedral
Carbon Atom 77

Amino Acids Can Join via Peptide Bonds 78

There Are 20 Common Amino Acids 78

Are There Other Ways to Classify Amino Acids? 82

A Deeper Look: Why Nature Chose Selenium 82

Amino Acids 21 and 22—and More? 83

Several Amino Acids Occur Only Rarely in Proteins 83

4.2 What Are the Acid–Base Properties of Amino Acids? 83

Amino Acids Are Weak Polyprotic Acids 83

**Critical Developments in Biochemistry: Adding New
Chemistry to Proteins with Unnatural Amino Acids 84**

Side Chains of Amino Acids Undergo Characteristic
Ionizations 86

4.3 What Reactions Do Amino Acids Undergo? 89

4.4 What Are the Optical and Stereochemical Properties of Amino Acids? 89

Amino Acids Are Chiral Molecules 89

Chiral Molecules Are Described by the D,L and (R,S)
Naming Conventions 90

**Critical Developments in Biochemistry: Green
Fluorescent Protein—The “Light Fantastic”—from
Jellyfish to Gene Expression 91**

4.5 What Are the Spectroscopic Properties of Amino Acids? 91

Phenylalanine, Tyrosine, and Tryptophan
Absorb Ultraviolet Light 92

Amino Acids Can Be Characterized by Nuclear Magnetic
Resonance 92

**Critical Developments in Biochemistry: Rules for
Description of Chiral Centers in the (R,S) System 93**

- 4.6 How Are Amino Acid Mixtures Separated and Analyzed? 94
Amino Acids Can Be Separated by Chromatography 94
- 4.7 What Is the Fundamental Structural Pattern in Proteins? 94
The Peptide Bond Has Partial Double-Bond Character 95
The Polypeptide Backbone Is Relatively Polar 97
Peptides Can Be Classified According to How Many Amino Acids They Contain 97
The Amino Acids in Polypeptides Can Be Released by Acid Hydrolysis 98
Proteins Are Composed of One or More Polypeptide Chains 98
- Foundational Biochemistry 100**
Problems 101
Further Reading 103

5

Proteins: Their Primary Structure and Biological Functions 105

- 5.1 What Architectural Arrangements Characterize Protein Structure? 105
Proteins Fall into Three Basic Classes According to Shape and Solubility 106
Protein Structure Is Described in Terms of Four Levels of Organization 107
Noncovalent Forces Drive Formation of the Higher Orders of Protein Structure 109
A Protein's Conformation Can Be Described as Its Overall Three-Dimensional Structure 109
- 5.2 How Are Proteins Isolated and Purified from Cells? 110
A Number of Protein Separation Methods Exploit Differences in Size and Charge 110
A Deeper Look: Estimation of Protein Concentrations in Solutions of Biological Origin 111
A Typical Protein Purification Scheme Uses a Series of Separation Methods 111
A Deeper Look: Techniques Used in Protein Purification 112
- 5.3 How Is the Primary Structure of a Protein Determined? 115
Sanger Was the First to Determine the Sequence of a Protein 116
Both Chemical and Enzymatic Methodologies Are Used in Protein Sequencing 116
Step 1. Separation of Polypeptide Chains 116
A Deeper Look: The Virtually Limitless Number of Different Amino Acid Sequences 117
Step 2. Cleavage of Disulfide Bridges 117
Step 3. N- and C-Terminal Analysis 117
Steps 4 and 5. Fragmentation of the Polypeptide Chain 119
- Step 6. Reconstruction of the Overall Amino Acid Sequence 120
The Amino Acid Sequence of a Protein Can Be Determined by Mass Spectrometry 122
Sequence Databases Contain the Amino Acid Sequences of Millions of Different Proteins 125
- 5.4 What Is the Nature of Amino Acid Sequences? 126
Homologous Proteins from Different Organisms Have Homologous Amino Acid Sequences 127
Computer Programs Can Align Sequences and Discover Homology between Proteins 127
Related Proteins Share a Common Evolutionary Origin 130
Apparently Different Proteins May Share a Common Ancestry 131
A Mutant Protein Is a Protein with a Slightly Different Amino Acid Sequence 131
- 5.5 How Are Polypeptides Synthesized in the Laboratory? 131
Orthogonal Synthesis of Peptides 132
Solid-Phase Methods Are Very Useful in Peptide Synthesis 132
- 5.6 Do Proteins Have Chemical Groups Other Than Amino Acids? 132
- 5.7 What Are the Many Biological Functions of Proteins? 134
Proteins Are the Agents of Biological Function 135
All Proteins Function through Specific Recognition and Binding of Some Target Molecule 135
- 5.8 What Is the Proteome and What Does It Tell Us? 137
The Proteome Is Large and Dynamic 137
Determining the Proteome of a Cell 137
Critical Developments in Biochemistry: Two New Suffixes in Molecular Biology and Biochemistry: “-ome” and “-omics” 138
A Deeper Look: The Human Proteome Project and the Human Protein Atlas 139
Foundational Biochemistry 139
Problems 140
Further Reading 142

6

Proteins: Secondary, Tertiary, and Quaternary Structure 145

- 6.1 What Noncovalent Interactions Stabilize the Higher Levels of Protein Structure? 146
Hydrogen Bonds Are Formed Whenever Possible 146
Hydrophobic Interactions Drive Protein Folding 146
Ionic Interactions Usually Occur on the Protein Surface 147
Van der Waals Interactions Are Ubiquitous 147

- 6.2 What Role Does the Amino Acid Sequence Play in Protein Structure? 147
- 6.3 What Are the Elements of Secondary Structure in Proteins, and How Are They Formed? 148
 The Amide Plane Is a Fundamental Determinant of All Protein Structure 148
 The Alpha-Helix Is a Key Secondary Structure 150
A Deeper Look: Knowing What the Right Hand and Left Hand Are Doing 150
Critical Developments in Biochemistry: X-ray Crystallography of Proteins 151
 The β -Pleated Sheet Is a Core Structure in Proteins 153
Critical Developments in Biochemistry: In Bed with a Cold, Pauling Stumbles onto the α -Helix and a Nobel Prize 154
 Helix–Sheet Composites Provide Flexibility and Strength in Spider Silk 156
 β -Turns Allow the Protein Strand to Change Direction 156
- 6.4 How Do Polypeptides Fold into Three-Dimensional Protein Structures? 157
A Deeper Look: The Coiled-Coil Motif in Proteins 158
 Fibrous Proteins Usually Play a Structural Role 159
 Globular Proteins Mediate Cellular Function 162
 Helices and Sheets Make Up the Core of Most Globular Proteins 162
Critical Developments in Biochemistry: The Protein Data Bank (PDB) 162
 Water Molecules on the Protein Surface Stabilize the Structure 163
 Packing Considerations 163
Human Biochemistry: Collagen-Related Diseases 164
 Protein Domains Are Nature's Modular Strategy for Protein Design 165
 Denaturation Leads to Loss of Protein Structure and Function 165
Human Biochemistry: Domain-Based Engineering of Proteins Forms the Basis of a Novel Cancer Treatment 167
 Anfinsen's Classic Experiment Proved That Sequence Determines Structure 169
 Is There a Single Mechanism for Protein Folding? 169
 What Is the Thermodynamic Driving Force for Protein Folding? 172
 Marginal Stability of the Tertiary Structure Makes Proteins Flexible 172
 Motion in Globular Proteins 172
 The Folding Tendencies and Patterns of Globular Proteins 173
A Deeper Look: Metamorphic Proteins—A Consequence of Dynamism and Marginal Stability 175
 Proteins Can Be Classified on the Basis of Folding Patterns 176
 Molecular Chaperones Are Proteins That Help Other Proteins to Fold 177
 Some Proteins Are Intrinsically Unstructured 178

Artificial Intelligence Algorithms Predict Protein Structures Accurately 180

Critical Developments in Biochemistry: NMR and Cryo-EM — Revolutionary Methods that Probe Protein Structure and Dynamics 180

- 6.5 How Do Protein Subunits Interact at the Quaternary Level of Protein Structure? 181

Human Biochemistry: Diseases of Protein Folding 182

Human Biochemistry: Structural Genomics 183

There Is Symmetry in Quaternary Structures 183

Quaternary Association Is Driven by Weak Forces 183

Open Quaternary Structures Can Polymerize 185

There Are Structural and Functional Advantages to Quaternary Association 185

Human Biochemistry: Faster-Acting Insulin: Genetic Engineering Solves a Quaternary Structure Problem 186

Foundational Biochemistry 188

Problems 188

Further Reading 190

7

Carbohydrates and the Glycoconjugates of Cell Surfaces 193

- 7.1 How Are Carbohydrates Named? 194

- 7.2 What Are the Structure and Chemistry of Monosaccharides? 194

Monosaccharides Are Classified as Aldoses and Ketoses 194

Stereochemistry Is a Prominent Feature of Monosaccharides 195

Monosaccharides Exist in Cyclic and Anomeric Forms 197

Haworth Projections Are a Convenient Device for Drawing Sugars 198

Monosaccharides Can Be Converted to Several Derivative Forms 200

A Deeper Look: Honey—An Ancestral Carbohydrate Treat 202

- 7.3 What Are the Structure and Chemistry of Oligosaccharides? 204

Disaccharides Are the Simplest Oligosaccharides 204

A Deeper Look: Trehalose—A Natural Protectant for Bugs 205

A Variety of Higher Oligosaccharides Occur in Nature 206

Human Biochemistry: Alpha-Gal and Red Meat Allergy 207

- 7.4 What Are the Structure and Chemistry of Polysaccharides? 208

Nomenclature for Polysaccharides Is Based on Their Composition and Structure 208

Polysaccharides Serve Energy Storage, Structure, and Protection Functions 209

Polysaccharides Provide Stores of Energy 209
 Polysaccharides Provide Physical Structure and Strength to Organisms 210
A Deeper Look: Ruth Benerito and Wrinkle-Free Cotton Fabrics 213
 Polysaccharides Provide Strength and Rigidity to Bacterial Cell Walls 214
A Deeper Look: A Complex Polysaccharide in Red Wine—The Strange Story of Rhamnogalacturonan II 215
 Animals Display a Variety of Cell Surface Polysaccharides 218

7.5 What Are Glycoproteins, and How Do They Function in Cells? 218

Carbohydrates on Proteins Can Be O-Linked or N-Linked 218
 O-GlcNAc Signaling Is Altered in Diabetes and Cancer 220
 O-Linked Saccharides Form Rigid Extended Extracellular Structures 220
 Polar Fish Depend on Antifreeze Glycoproteins 220
 N-Linked Oligosaccharides Can Affect the Physical Properties and Functions of a Protein 221
Human Biochemistry: Drug Research Finds a Sweet Spot 222
 Sialic Acid Terminates the Oligosaccharides of Glycoproteins and Glycolipids 222
 Sialic Acid Cleavage Can Serve as a Timing Device for Protein Degradation 223

7.6 How Do Proteoglycans Modulate Processes in Cells and Organisms? 224

Functions of Proteoglycans Involve Binding to Other Proteins 225
 Proteoglycans May Modulate Cell Growth Processes 226
 Proteoglycans Make Cartilage Flexible and Resilient 226

7.7 How Do Carbohydrates Provide a Structural Code? 226

Lectins Translate the Sugar Code 228
 Selectins, Rolling Leukocytes, and the Inflammatory Response 228
 Galectins—Mediators of Inflammation, Immunity, and Cancer 229

Foundational Biochemistry 231

Problems 231

Further Reading 234

Lipids 237

- 8.1 What Are the Structures and Chemistry of Fatty Acids? 237
- 8.2 What Are the Structures and Chemistry of Triacylglycerols? 241
A Deeper Look: Polar Bears Prefer Nonpolar Food 242

- 8.3 What Are the Structures and Chemistry of Glycerophospholipids? 242
 Glycerophospholipids Are the Most Common Phospholipids 243
 Ether Glycerophospholipids Include PAF and Plasmalogens 245
Human Biochemistry: Platelet-Activating Factor: A Potent Ether Glycerophospholipid Mediator 246
- 8.4 What Are Sphingolipids, and How Are They Important for Higher Animals? 246
- 8.5 What Are Waxes, and How Are They Used? 246
A Deeper Look: Novel Lipids with Valuable Properties 248
- 8.6 What Are Terpenes, and What Is Their Relevance to Biological Systems? 249
A Deeper Look: Why Do Plants Emit Isoprene? 251
Human Biochemistry: Coumadin or Warfarin—Agent of Life or Death 251
- 8.7 What Are Steroids, and What Are Their Cellular Functions? 252
 Cholesterol 252
 Steroid Hormones Are Derived from Cholesterol 252
Human Biochemistry: Plant Sterols and Stanols—Natural Cholesterol Fighters 254
- 8.8 How Do Lipid Metabolites Act as Biological Signals? 254
Human Biochemistry: Beating COVID-19: Lipid Nanoparticles Make RNA Vaccines Practical and Effective 255
Human Biochemistry: The Endocannabinoid Signaling System: A Target for Next-Generation Therapeutics 256
Human Biochemistry: Fingolimod—a Sphingosine-1-P Mimic Is an Oral Drug for Multiple Sclerosis 258
- 8.9 What Can Lipidomics Tell Us about Cell, Tissue, and Organ Physiology? 259
Foundational Biochemistry 261
Problems 261

9

Membranes and Membrane Transport 265

- 9.1 What Are the Chemical and Physical Properties of Membranes? 266
 The Composition of Membranes Suits Their Functions 266
 Lipids Form Ordered Structures Spontaneously in Water 267
 The Fluid Mosaic Model Describes Membrane Dynamics 269
- 9.2 What Are the Structure and Chemistry of Membrane Proteins? 271

Peripheral Membrane Proteins Associate Loosely with the Membrane 271

Integral Membrane Proteins Are Firmly Anchored in the Membrane 271

Lipid-Anchored Membrane Proteins Can Act as Switching Devices 280

9.3 How Are Biological Membranes Organized? 282

9.4 What Are the Dynamic Processes That Modulate Membrane Function? 283

Lipids and Proteins Undergo a Variety of Movements in Membranes 283

Membrane Lipids Can Be Ordered to Different Extents 284

9.5 How Does Transport Occur across Biological Membranes? 293

9.6 What Is Passive Diffusion? 294

9.7 How Does Facilitated Diffusion Occur? 294

Membrane Channel Proteins Facilitate Diffusion 295

The *Bacillus cereus* NaK Channel Uses a Variation on the K⁺ Selectivity Filter 297

CorA Is a Pentameric Mg²⁺ Channel 298

Chloride, Water, Glycerol, and Ammonia Flow through Single-Subunit Pores 299

9.8 How Does Energy Input Drive Active Transport Processes? 300

All Active Transport Systems Are Energy-Coupling Devices 300

Many Active Transport Processes Are Driven by ATP 301

A Deeper Look: Cardiac Glycosides: Potent Drugs from Ancient Times 305

ABC Transporters Use ATP to Drive Import and Export Functions and Provide Multidrug Resistance 306

9.9 How Are Certain Transport Processes Driven by Light Energy? 308

9.10 How Is Secondary Active Transport Driven by Ion Gradients? 310

Na⁺ and H⁺ Drive Secondary Active Transport 310

AcrB Is a Secondary Active Transport System 310

Foundational Biochemistry 311

Problems 312

Further Reading 314

10

Nucleotides and Nucleic Acids 317

10.1 What Are the Structure and Chemistry of Nitrogenous Bases? 318

Three Pyrimidines and Two Purines Are Commonly Found in Cells 318

The Properties of Pyrimidines and Purines Can Be Traced to Their Electron-Rich Nature 319

10.2 What Are Nucleosides? 319

Human Biochemistry: Adenosine: A Nucleoside with Physiological Activity 320

10.3 What Are the Structure and Chemistry of Nucleotides? 320

Cyclic Nucleotides Are Cyclic Phosphodiesterases 322

Nucleoside Diphosphates and Triphosphates Are Nucleotides with Two or Three Phosphate Groups 322

Human Biochemistry: cGAMP, a Cyclic Dinucleotide That Triggers a Response to Infection 322

NDPs and NTPs Are Polyprotic Acids 323

Nucleoside 5'-Triphosphates Are Carriers of Chemical Energy 323

10.4 What Are Nucleic Acids? 324

The Base Sequence of a Nucleic Acid Is Its Defining Characteristic 325

10.5 What Are the Different Classes of Nucleic Acids? 326

The Fundamental Structure of DNA Is a Double Helix 326

Various Forms of RNA Serve Different Roles in Cells 330

A Deeper Look: The RNA World and Early Evolution 334

The Chemical Differences between DNA and RNA Have Biological Significance 334

10.6 Are Nucleic Acids Susceptible to Hydrolysis? 335

RNA Is Susceptible to Hydrolysis by Base, but DNA Is Not 335

The Enzymes That Hydrolyze Nucleic Acids Are Phosphodiesterases 335

Nucleases Differ in Their Specificity for Different Forms of Nucleic Acid 335

Restriction Enzymes Are Nucleases That Cleave Double-Stranded DNA Molecules 337

Type II Restriction Endonucleases Are Useful for Manipulating DNA in the Lab 337

Restriction Endonucleases Can Be Used to Map the Structure of a DNA Fragment 339

Foundational Biochemistry 341

Problems 341

Further Reading 343

11

Structure of Nucleic Acids 345

11.1 How Do Scientists Determine the Primary Structure of Nucleic Acids? 345

The Nucleotide Sequence of DNA Can Be Determined from the Electrophoretic Migration of a Defined Set of Polynucleotide Fragments 346

Sanger's Chain Termination or Dideoxy Method Uses DNA Replication to Generate a Defined Set of Polynucleotide Fragments 346

- Next-Generation Sequencing by Synthesis 348
- High-Throughput DNA Sequencing Based on Proton Detection 349
- Single-Molecule Real-Time Sequencing 351
- Human Biochemistry: The Human Genome Project 352**
- Oxford Nanopore Technologies (ONT) Real-Time Sequencing 352
- Bioinformatics—Functional Genomics, Proteomics, and More 353
- 11.2 What Sorts of Secondary Structures Can Double-Stranded DNA Molecules Adopt? 354**
 - Conformational Variation in Polynucleotide Strands 354
 - DNA Usually Occurs in the Form of Double-Stranded Helices 355
 - Watson–Crick Base Pairs Have Virtually Identical Dimensions 355
 - The DNA Double Helix Is a Stable Structure 355
 - Double Helical Structures Can Adopt a Number of Stable Conformations 357
 - A-Form DNA Is an Alternative Form of Right-Handed DNA 357
 - Z-DNA Is a Conformational Variation in the Form of a Left-Handed Double Helix 358
 - The Double Helix Is Flexible 361
 - Human Biochemistry: DNA Methylation, CpG Islands, and Epigenetics 362**
 - Alternative Hydrogen-Bonding Interactions Give Rise to Novel DNA Structures: Cruciforms, Triplexes, and Quadruplexes 362
- 11.3 Can the Secondary Structure of DNA Be Denatured and Renatured? 366**
 - Thermal Denaturation of DNA Can Be Observed by Changes in UV Absorbance 367
 - pH Extremes or Strong H-Bonding Solutes also Denature DNA Duplexes 367
 - Single-Stranded DNA Can Renature to Form DNA Duplexes 367
 - A Deeper Look: The Buoyant Density of DNA 368**
 - The Rate of DNA Renaturation Is an Index of DNA Sequence Complexity 368
 - Nucleic Acid Hybridization: Different DNA Strands of Similar Sequence Can Form Hybrid Duplexes 369
- 11.4 How Does DNA Adopt Structures of Higher Complexity? 370**
 - Supercoils Are One Kind of Structural Complexity in DNA 370
 - Supercoiled DNA Is Defined by Its Linking Number 370
 - Enzymes Can Add or Remove Supercoils 371
- 11.5 What Is the Structure of Eukaryotic Chromosomes? 372**
 - Nucleosomes Are the Fundamental Structural Unit in Chromatin 373
 - Higher-Order Structural Organization of Chromatin Gives Rise to Chromosomes 374

SMC Proteins Establish Chromosome Organization and Mediate Chromosome Dynamics 375

11.6 How Can Nucleic Acids Be Synthesized Chemically? 375

Phosphoramidite Chemistry Is Used to Form Oligonucleotides from Nucleotides 376

Genes and Even Chromosomes Can Be Synthesized Chemically 376

11.7 What Are the Secondary and Tertiary Structures of RNA? 378

Transfer RNA Adopts Higher-Order Structure Through Intrastrand Base Pairing 380

Messenger RNA Adopts Higher-Order Structure Through Intrastrand Base Pairing 381

Ribosomal RNA Also Adopts Higher-Order Structure Through Intrastrand Base Pairing 382

Aptamers Are Oligonucleotides Specifically Selected for Their Ligand-Binding Ability 384

Recombinant DNA, Cloning, Gene Editing, and Synthetic Biology—An Introduction 393

12.1 What Is DNA Cloning? 394

Plasmids Are Very Useful in Cloning Genes 394

Shuttle Vectors Are Plasmids That Can Propagate in Two Different Organisms 399

Artificial Chromosomes Can Be Created from Recombinant DNA 399

12.2 What Is a DNA Library? 400

Genomic Libraries Are Prepared from the Total DNA in an Organism 400

Critical Developments in Biochemistry: Combinatorial Libraries 400

Libraries Can Be Screened for the Presence of Specific Genes 401

Probes for Screening Libraries Can Be Prepared in a Variety of Ways 402

PCR Is Used to Clone and Amplify Specific Genes 402

Critical Developments in Biochemistry: Identifying Specific DNA Sequences by Southern Blotting (Southern Hybridization) 404

cDNA Libraries Are DNA Libraries Prepared from mRNA 405

DNA Microarrays (*Gene Chips*) Are Arrays of Different Oligonucleotides Immobilized on a Chip 407

12.3 Can the Genes in Libraries Be Transcribed and Translated? 408

Expression Vectors Are Engineered So That the RNA or Protein Products of Cloned Genes Can Be Synthesized 408

Reporter Gene Constructs Are Chimeric DNA Molecules Composed of Gene Regulatory Sequences Positioned Next to an Easily Expressible Gene Product 411

Specific Protein–Protein Interactions Can Be Identified Using the Yeast Two-Hybrid System 412

In Vitro Mutagenesis—Introducing Changes into Expressed Proteins 413

12.4 How Is RNA Interference Used to Reveal the Function of Genes? 413

12.5 Gene Therapy: Is It Possible for Scientists to Alter or Rewrite the Genome of an Organism? 414

Human Gene Therapy Can Repair Genetic Deficiencies 415

13

Enzymes—Kinetics and Specificity 433

Enzymes Are the Agents of Metabolic Function 434

13.1 What Characteristic Features Define Enzymes? 434

Catalytic Power Is Defined as the Ratio of the Enzyme-Catalyzed Rate of a Reaction to the Uncatalyzed Rate 435

Specificity Is the Term Used to Define the Selectivity of Enzymes for Their Substrates 435

Regulation of Enzyme Activity Ensures That the Rate of Metabolic Reactions Is Appropriate to Cellular Requirements 435

Enzyme Nomenclature Provides a Systematic Way of Naming Metabolic Reactions 435

Coenzymes and Cofactors Are Nonprotein Components Essential to Enzyme Activity 437

13.2 How Can the Rate of an Enzyme-Catalyzed Reaction Be Defined in a Mathematical Way? 438

Chemical Kinetics Provides a Foundation for Exploring Enzyme Kinetics 438

Bimolecular Reactions Are Reactions Involving Two Reactant Molecules 439

Catalysts Lower the Free Energy of Activation for a Reaction 439

Decreasing $\Delta G^\ddagger$ Increases Reaction Rate 440

13.3 What Equations Define the Kinetics of Enzyme-Catalyzed Reactions? 441

The Substrate Binds at the Active Site of an Enzyme 441

The Michaelis–Menten Equation Is the Fundamental Equation of Enzyme Kinetics 442

Rate Calculations Assume That $[ES]$ Remains Constant During an Enzymatic Reaction 442

A Calculations Are Simplified If Velocity Measurements Are Made Immediately after Adding S 442

The Michaelis Constant, K_m , Is Defined as $(k_{-1} + k_2)/k_1$ 443

When $[S] = K_m$, $v = V_{max}/2$ 444

Plots of v versus $[S]$ Illustrate the Relationships between V_{max} , K_m , and Reaction Order 444

Turnover Number Defines the Activity of One Enzyme Molecule 445

The Ratio, k_{cat}/K_m , Defines the Catalytic Efficiency of an Enzyme 445

Linear Plots Can Be Derived from the Michaelis–Menten Equation 446

A Deeper Look: An Example of the Effect of Amino Acid Substitutions on K_m and k_{cat} : Wild-Type and Mutant Forms of Human Sulfite Oxidase 448

Nonlinear Lineweaver–Burk or Hanes–Woolf Plots Are a Property of Regulatory Enzymes 448

Enzymatic Activity Is Strongly Influenced by pH 448

The Response of Enzymatic Activity to Temperature Is Complex 448

13.4 What Can Be Learned from the Inhibition of Enzyme Activity? 449

Enzymes May Be Inhibited Reversibly or Irreversibly 449

Reversible Inhibitors May Bind at the Active Site or at Some Other Site 450

A Deeper Look: The Equations of Competitive Inhibition 451

Enzymes Also Can Be Inhibited in an Irreversible Manner 453

13.5 What Is the Kinetic Behavior of Enzymes Catalyzing Bimolecular Reactions? 455

Human Biochemistry: Viagra—An Unexpected Outcome in a Program of Drug Design 456

The Conversion of AEB to PEQ Is the Rate-Limiting Step in Random, Single-Displacement Reactions 457

In an Ordered, Single-Displacement Reaction, the Leading Substrate Must Bind First 458

Double-Displacement (Ping-Pong) Reactions Proceed Via Formation of a Covalently Modified Enzyme Intermediate 459

Exchange Reactions Are One Way to Diagnose Bisubstrate Mechanisms 461

Multisubstrate Reactions Can Also Occur in Cells 461

13.6 How Can Enzymes Be So Specific? 461

The Lock-and-Key Hypothesis Was the First Explanation for Specificity 462

The Induced-Fit Hypothesis Provides a More Accurate Description of Specificity 462

Induced Fit Favors Formation of the Transition State 462
Specificity and Reactivity 462

13.7 Are All Enzymes Proteins? 463

RNA Molecules That Are Catalytic Have Been Termed Ribozymes 463

Antibody Molecules Can Have Catalytic Activity 464

13.8 Is It Possible to Design an Enzyme to Catalyze Any Desired Reaction? 466

A Designer Enzyme for Bioremediation 467

A Case Study for Designer Enzyme Development — Kemp Eliminases 467

15

Enzyme Regulation 511

15.1 What Factors Influence Enzymatic Activity? 511

The Availability of Substrates and Cofactors Usually Determines How Fast the Reaction Goes 512

As Product Accumulates, the Apparent Rate of the Enzymatic Reaction Will Decrease 512

Genetic Regulation of Enzyme Synthesis Determines the Amount of Enzyme Present at Any Moment 512

Enzyme Activity Can Be Regulated Allosterically 512

Enzyme Activity Can Be Regulated through Covalent Modification 513

Zymogens Are Inactive Precursors of Enzymes 513

Isozymes Are Enzymes with Slightly Different Subunits and Kinetic Properties 514

15.2 What Are the General Features of Allosteric Regulation? 516

Regulatory Enzymes Have Certain Exceptional Properties 516

15.3 Can Allosteric Regulation Be Explained by Conformational Changes in Proteins? 517

The Symmetry Model for Allosteric Regulation Is Based on Two Conformational States for a Protein 517

The Sequential Model for Allosteric Regulation Is Based on Ligand-Induced Conformational Changes 517

The Notable Difference between the MWC and KNF Models 519

Changes in the Oligomeric State of a Protein Can Also Give Allosteric Behavior 519

- 15.4 What Kinds of Covalent Modification Regulate the Activity of Enzymes? 519**
 Covalent Modification through Reversible Phosphorylation 519
 Protein Kinases: Target Recognition and Intrasteric Control 519
 Phosphorylation Is Not the Only Form of Covalent Modification That Regulates Enzyme Function 522
 Acetylation Is a Prominent Modification for the Regulation of Metabolic Enzymes 522
- 15.5 Is the Activity of Some Enzymes Controlled by Both Allosteric Regulation and Covalent Modification? 523**
 The Glycogen Phosphorylase Reaction Converts Glycogen into Readily Usable Fuel in the Form of Glucose-1-Phosphate 523
 Glycogen Phosphorylase Is a Homodimer 523
 Glycogen Phosphorylase Activity Is Regulated Allosterically 524
 Covalent Modification of Glycogen Phosphorylase Overrides Allosteric Regulation 526
 Enzyme Cascades Regulate Glycogen Phosphorylase Covalent Modification 526
- 15.6 What Is the Relationship between Quaternary Structure and Allosteric Regulation? 528**
 The Comparative Biochemistry of Myoglobin and Hemoglobin Reveals Insights into Allostery 528
 Myoglobin Is an Oxygen-Storage Protein 529
 O_2 Binds to the Mb Heme Group 529
 O_2 Binding Alters Mb Conformation 529
A Deeper Look: The Oxygen-Binding Curves of Myoglobin and Hemoglobin 530
 Cooperative Binding of Oxygen by Hemoglobin Has Important Physiological Significance 531
 Hemoglobin Has an $\alpha_2\beta_2$ Tetrameric Structure 531
 Oxygenation Markedly Alters the Quaternary Structure of Hb 532
 Movement of the Heme Iron by Less Than 0.04 nm Induces the Conformational Change in Hemoglobin 532
 The Physiological Significance of the Hb: O_2 Interaction 532
 The Oxy and Deoxy Forms of Hemoglobin Represent Two Different Conformational States 533
 The Allosteric Behavior of Hemoglobin Has Both Symmetry (MWC) Model and Sequential (KNF) Model Components 533
 H^+ Promotes the Dissociation of Oxygen from Hemoglobin 533
 CO_2 Also Promotes the Dissociation of O_2 from Hemoglobin 534
 2,3-Bisphosphoglycerate Is an Important Allosteric Effector for Hemoglobin 535
 BPG Binding to Hb Has Important Physiological Significance 535
 Fetal Hemoglobin Has a Higher Affinity for O_2 Because It Has a Lower Affinity for BPG 535

Human Biochemistry: Hemoglobin and Nitric Oxide 536

Sickle-Cell Disease Is Characterized by Abnormal Red Blood Cells 537

Sickle-Cell Disease Has Been Characterized as a Molecular Disease 537

Molecular Motors 543

- 16.1 What Are the General Features of Molecular Motors? 543**
- 16.2 What Is the Molecular Mechanism of Muscle Contraction? 544**
 Muscle Contraction Is Triggered by Ca^{2+} Release from Intracellular Stores 544
Human Biochemistry: Medical Applications of Smooth Muscle Effectors 545
 The Molecular Structure of Skeletal Muscle Is Based on Actin and Myosin 545
 The Mechanism of Muscle Contraction Is Based on Sliding Filaments 548
A Deeper Look: The P-Loop NTPases—Energy to Run the Motors 549
- 16.3 What Are the Molecular Motors That Orchestrate the Mechanochemistry of Microtubules? 551**
 Filaments of the Cytoskeleton Are Highways That Move Cellular Cargo 552
 Three Classes of Motor Proteins Move Intracellular Cargo 553
 Dyneins Move Organelles in a Plus-to-Minus Direction; Kinesins, in a Minus-to-Plus Direction 554
Human Biochemistry: Effectors of Microtubule Polymerization as Therapeutic Agents 555
 Cytoskeletal Motors Are Highly Processive 555
 ATP Binding and Hydrolysis Drive Hand-over-Hand Movement of Kinesin 557
 Conformation Changes in a Hexameric Ring Drive the Dynein Motor 558
- 16.4 How Do Molecular Motors Unwind DNA? 558**
 Negative Cooperativity Facilitates Hand-over-Hand Movement 561
 Papillomavirus E1 Helicase Moves along DNA as on a Spiral Staircase 562
- 16.5 How Do Bacterial Flagella Use a Proton Gradient to Drive Rotation? 564**
 The Flagellar Rotor Is a Complex Structure 565
 Gradients of H^+ and Na^+ Drive Flagellar Rotors 565
 The Flagellar Rotor Self-Assembles in a Spontaneous Process 565

Flagellar Filaments Are Composed of Protofilaments of Flagellin 566

Motor Reversal Involves Conformation Switching of Motor and Filament Proteins 566

Foundational Biochemistry 568

Problems 568

Part III Metabolism and Its Regulation 573

17

Metabolism: An Overview 573

- 17.1 Is Metabolism Similar in Different Organisms? 573
 - Living Things Vary in Their Carbon and Energy Requirements 574
 - Oxygen Is Essential to Life for Aerobes 574
 - The Flow of Energy in the Biosphere and the Carbon and Oxygen Cycles Are Intimately Related 574
 - A Deeper Look: Calcium Carbonate—A Biological Sink for CO₂ 575**
- 17.2 What Can Be Learned from Metabolic Maps? 575
 - The Metabolic Map Can Be Viewed as a Set of Dots and Lines 575
 - Alternative Metabolic Pathway Models Can Provide New Insights into Pathways 577
 - Metabolism Is a Network 578
 - Metabolic Pathways with Multiple Enzymes May Take Different Forms 579
- 17.3 How Do Anabolic and Catabolic Processes Form the Core of Metabolic Pathways? 580
 - Anabolism Is Biosynthesis 580
 - Anabolism and Catabolism Are Not Mutually Exclusive 580
 - The Pathways of Catabolism Converge to a Few End Products 581
 - Anabolic Pathways Diverge, Synthesizing an Astounding Variety of Biomolecules from a Limited Set of Building Blocks 581
 - Amphibolic Intermediates Play Dual Roles 583
 - Corresponding Pathways of Catabolism and Anabolism Differ in Important Ways 583
 - Metabolic Regulation Requires Different Pathways for Oppositely Directed Metabolic Sequences 583
 - ATP Is Produced and Consumed in a Cellular Energy Cycle 583
 - NAD⁺ Collects Electrons Released in Catabolism 584
 - NADPH Provides the Reducing Power for Anabolic Processes 585
 - Coenzymes and Vitamins Provide Unique Chemistry and Essential Nutrients to Pathways 586
- 17.4 What Experiments Can Be Used to Elucidate Metabolic Pathways? 587
 - Enzyme Inhibitors Can Be Used to Reveal Individual Metabolic Reactions 587

Mutations Create Specific Metabolic Blocks 588

Isotopic Tracers Can Be Used as Metabolic Probes 588

NMR Spectroscopy Is a Noninvasive Metabolic Probe 589

Cell Fractionation Reveals Which Compartment Contains a Metabolic Pathway 589

Metabolic Pathways Are Also Time-Dependent 591

- 17.5 What Can the Metabolome Tell Us about a Biological System? 592

- 17.6 What Food Substances Form the Basis of Human Nutrition? 596

Humans Require Protein 596

Carbohydrates Provide Metabolic Energy 597

Lipids Are Essential, but in Moderation 597

Foundational Biochemistry 597

Problems 598

Glycolysis 603

- 18.1 What Are the Essential Features of Glycolysis? 603
- 18.2 Why Are Coupled Reactions Important in Glycolysis? 605
- 18.3 What Are the Chemical Principles and Features of the First Phase of Glycolysis? 606
 - Reaction 1: Glucose Is Phosphorylated by Hexokinase or Glucokinase—The First Priming Reaction 606
 - A Deeper Look: Glucokinase—An Enzyme with Different Roles in Different Cells 609**
 - Reaction 2: Phosphoglucosomerase Catalyzes the Isomerization of Glucose-6-Phosphate 609
 - Reaction 3: ATP Drives a Second Phosphorylation by Phosphofructokinase—The Second Priming Reaction 610
 - Reaction 4: Cleavage by Fructose Bisphosphate Aldolase Creates Two 3-Carbon Intermediates 612
 - Reaction 5: Triose Phosphate Isomerase Completes the First Phase of Glycolysis 613
 - Human Biochemistry: Methylglyoxal and Advanced Glycation End-Products—The Dark Side of Glycolysis 614**
- 18.4 What Are the Chemical Principles and Features of the Second Phase of Glycolysis? 615
 - Reaction 6: Glyceraldehyde-3-Phosphate Dehydrogenase Creates a High-Energy Intermediate 615
 - Reaction 7: Phosphoglycerate Kinase Is the Break-Even Reaction 615
 - Reaction 8: Phosphoglycerate Mutase Catalyzes a Phosphoryl Transfer 617
 - Reaction 9: Dehydration by Enolase Creates PEP 618
 - Reaction 10: Pyruvate Kinase Yields More ATP 618
 - Human Biochemistry: Pyruvate Kinase M2 Moonlights as a Protein Kinase in Cancer 620**

- 18.5 What Are the Metabolic Fates of NADH and Pyruvate Produced in Glycolysis? 621
 Anaerobic Metabolism of Pyruvate Leads to Lactate or Ethanol 621
 Lactate Accumulates Under Anaerobic Conditions in Animal Tissues 622
Critical Developments in Biochemistry: The Warburg Effect and Cancer 623
- 18.6 How Do Cells Regulate Glycolysis? 624
- 18.7 Are Substrates Other Than Glucose Used in Glycolysis? 624
 Fructose Catabolism in Liver Is Unregulated—and Potentially Harmful 624
 Mannose Enters Glycolysis in Two Steps 626
 Galactose Enters Glycolysis via the Leloir Pathway 626
Human Biochemistry: Tumor Diagnosis Using Positron Emission Tomography (PET) 626
 Glycerol Can Also Enter Glycolysis 628
- 18.8 How Do Cells Respond to Hypoxic Stress? 628
Human Biochemistry: Lactose and Lactose Intolerance: From Mother's Milk to Yogurt 629
Foundational Biochemistry 631
Problems 631

The Tricarboxylic Acid Cycle 635

- 19.1 What Is the Chemical Logic of the TCA Cycle? 636
- 19.2 How Is Pyruvate Oxidatively Decarboxylated to Acetyl-CoA? 639
A Deeper Look: The Coenzymes of the Pyruvate Dehydrogenase Complex 642
- 19.3 How Are Two CO₂ Molecules Produced from Acetyl-CoA? 644
 The Citrate Synthase Reaction Initiates the TCA Cycle 644
 Citrate Is Isomerized by Aconitase to Form Isocitrate 645
 Isocitrate Dehydrogenase Catalyzes the First Oxidative Decarboxylation in the Cycle 647
 α -Ketoglutarate Dehydrogenase Catalyzes the Second Oxidative Decarboxylation of the TCA Cycle 648
- 19.4 How Is Oxaloacetate Regenerated to Complete the TCA Cycle? 648
 Succinyl-CoA Synthetase Catalyzes Substrate-Level Phosphorylation 649
 Succinate Dehydrogenase Is FAD-Dependent 650
 Fumarase Catalyzes the *Trans*-Hydration of Fumarate to Form L-Malate 650
 Malate Dehydrogenase Completes the Cycle by Oxidizing Malate to Oxaloacetate 651

- 19.5 What Are the Energetic Consequences of the TCA Cycle? 651
 The Carbon Atoms of Acetyl-CoA Have Different Fates in the TCA Cycle 652
A Deeper Look: Steric Preferences in NAD⁺-Dependent Dehydrogenases 654
- 19.6 Can the TCA Cycle Provide Intermediates for Biosynthesis? 654
Human Biochemistry: Leber's Hereditary Optic Neuropathy Arises from Mitochondrial DNA Mutations 655
- 19.7 What Are the Anaplerotic, or Filling Up, Reactions? 656
A Deeper Look: Anaplerosis Plays a Critical Role in Insulin Secretion 657
A Deeper Look: Fool's Gold and the Reductive Citric Acid Cycle—The First Metabolic Pathway? 658
- 19.8 How Is the TCA Cycle Regulated? 658
 Pyruvate Dehydrogenase Is Regulated by Phosphorylation/Dephosphorylation 659
 Isocitrate Dehydrogenase Is Strongly Regulated 660
 Regulation of TCA Cycle Enzymes by Acetylation 660
Human Biochemistry: TCA Metabolites Play Roles in Many Pathways via Post-Translational Modifications 661
 Two Covalent Modifications Regulate *E. coli* Isocitrate Dehydrogenase 661
 TCA Metabolites Can Act as Cellular Signals 662
 The TCA Cycle Operates as a Metabolon 662
- 19.9 Can Any Organisms Use Acetate as Their Sole Carbon Source? 662
 The Glyoxylate Cycle Operates in Specialized Organelles 663
 Isocitrate Lyase Short-Circuits the TCA Cycle by Producing Glyoxylate and Succinate 664
 The Glyoxylate Cycle Helps Plants Grow in the Dark 665
 Glyoxysomes Must Borrow Three Reactions from Mitochondria 665
Foundational Biochemistry 666

Electron Transport and Oxidative Phosphorylation 671

- 20.1 Where in the Cell Do Electron Transport and Oxidative Phosphorylation Occur? 671
 Mitochondrial Functions Are Localized in Specific Compartments 672
Human Biochemistry: Mitochondrial Dynamics in Human Diseases 673
 The Mitochondrial Matrix Contains the Enzymes of the TCA Cycle 674

- 20.2 How Is the Electron-Transport Chain Organized? 674**
 The Electron-Transport Chain Can Be Isolated in Four Complexes 675
 Complex I Oxidizes NADH and Reduces Coenzyme Q 676
Human Biochemistry: Solving a Medical Mystery Revolutionized Our Treatment of Parkinson's Disease 679
 Complex II Oxidizes Succinate and Reduces Coenzyme Q 680
 Complex III Mediates Electron Transport from Coenzyme Q to Cytochrome *c* 681
 Complex IV Transfers Electrons from Cytochrome *c* to Reduce Oxygen on the Matrix Side 684
 Proton Transport Across Cytochrome *c* Oxidase Is Coupled to Oxygen Reduction 686
 Reversal of Complex II May Short-Circuit the Electron Transfer Pathway 687
 The Complexes of Electron Transport May Function as Supercomplexes 687
 Electron Transfer Energy Stored in a Proton Gradient: The Mitchell Hypothesis 689
- 20.3 What Are the Thermodynamic Implications of Chemiosmotic Coupling? 690**
- 20.4 How Does a Proton Gradient Drive the Synthesis of ATP? 690**
 ATP Synthase Is Composed of F_1 and F_0 Complexes 691
 The Catalytic Sites of ATP Synthase Adopt Three Different Conformations 693
 Boyer's ^{18}O Exchange Experiment Identified the Energy-Requiring Step 693
 The Binding Change Mechanism Describes the Events of Rotational Catalysis 694
 Proton Flow Through F_0 Drives Rotation of the Motor and Synthesis of ATP 694
 How Many Protons Are Required to Make an ATP? It Depends on the Organism 696
 The Mitchell Model Has Been Confirmed in a Reconstitution Experiment 696
 Inhibitors of Oxidative Phosphorylation Reveal Insights About the Mechanism 697
 Uncouplers Disrupt the Coupling of Electron Transport and ATP Synthase 698
 ATP–ADP Translocase Mediates the Movement of ATP and ADP Across the Mitochondrial Membrane 698
Human Biochemistry: Endogenous Uncouplers—Novel Proteins with Many Beneficial Effects 699
- 20.5 What Is the P/O Ratio for Mitochondrial Oxidative Phosphorylation? 700**
- 20.6 How Are the Electrons of Cytosolic NADH Fed into Electron Transport? 701**
 The Glycerophosphate Shuttle Ensures Efficient Use of Cytosolic NADH 701
 The Malate–Aspartate Shuttle Is Reversible 702
 The Net Yield of ATP from Glucose Oxidation Depends on the Shuttle Used 703
 3.5 Billion Years of Evolution Have Resulted in a Very Efficient System 704

- 20.7 How Do Mitochondria Mediate Apoptosis? 704**
 Cytochrome *c* Triggers Apoptosome Assembly 706
Foundational Biochemistry 707
Problems 707

21

Photosynthesis 713

- 21.1 What Are the General Properties of Photosynthesis? 714**
 Photosynthesis Occurs in Membranes 714
 Photosynthesis Consists of Both Light Reactions and Dark Reactions 715
 Water Is the Ultimate Electron Donor for Photosynthetic NADP^+ Reduction 716
- 21.2 How Is Solar Energy Captured by Chlorophyll? 717**
 Chlorophylls and Accessory Light-Harvesting Pigments Absorb Light of Different Wavelengths 717
 The Light Energy Absorbed by Photosynthetic Pigments Has Several Possible Fates 718
 The Transduction of Light Energy into Chemical Energy Involves Oxidation–Reduction 719
 Photosynthetic Units Consist of Many Chlorophyll Molecules but Only a Single Reaction Center 720
- 21.3 What Kinds of Photosystems Are Used to Capture Light Energy? 721**
 Chlorophyll Exists in Plant Membranes in Association with Proteins 721
 PSI and PSII Participate in the Overall Process of Photosynthesis 721
 The Pathway of Photosynthetic Electron Transfer Is Called the Z Scheme 722
 Oxygen Evolution Requires the Accumulation of Four Oxidizing Equivalents in PSII 722
 Electrons Are Taken from H_2O to Replace Electrons Lost from P680 724
 Electrons from PSII Are Transferred to PSI via the Cytochrome b_6f Complex 724
 Plastocyanin Transfers Electrons from the Cytochrome b_6f Complex to PSI 724
- 21.4 What Is the Molecular Architecture of Photosynthetic Reaction Centers? 725**
 The *R. viridis* Photosynthetic Reaction Center Is an Integral Membrane Protein 725
 Photosynthetic Electron Transfer by the *R. viridis* Reaction Center Leads to ATP Synthesis 726
 The Molecular Architecture of PSII Resembles the *R. viridis* Reaction Center Architecture 727
 How Does PSII Generate O_2 from H_2O ? 729
 The Molecular Architecture of PSI Resembles the *R. viridis* Reaction Center and PSII Architecture 730
 How Do Green Plants Carry Out Photosynthesis? 731

- 21.5 What Is the Quantum Yield of Photosynthesis? 731
The H^+ /ATP Ratio Determines ATP Yield per Quantum 732
Calculation of the Photosynthetic Energy Requirements for Hexose Synthesis Depends on $H^+/h\nu$ and ATP/ H^+ Ratios 732
- 21.6 How Does Light Drive the Synthesis of ATP? 732
The Mechanism of Photophosphorylation Is Chemiosmotic 733
 CF_0CF_1 -ATP Synthase Is the Chloroplast Equivalent of the Mitochondrial F_1F_0 -ATP Synthase 733
Photophosphorylation Can Occur in Either a Noncyclic or a Cyclic Mode 733
Cyclic Photophosphorylation Generates ATP but Not NADPH or O_2 734
- 21.7 How Is Carbon Dioxide Used to Make Organic Molecules? 735
Ribulose-1,5-Bisphosphate Is the CO_2 Acceptor in CO_2 Fixation 736
2-Carboxy-3-Keto-Arabinitol Is an Intermediate in the Ribulose-1,5-Bisphosphate Carboxylase Reaction 736
Ribulose-1,5-Bisphosphate Carboxylase Exists in Inactive and Active Forms 737
 CO_2 Fixation into Carbohydrate Proceeds via the Calvin–Benson Cycle 737
Rubisco and the Enzymes of the Calvin Cycle Serve Three Metabolic Purposes 738
The Calvin Cycle Reactions Can Account for Net Hexose Synthesis 740
The Carbon Dioxide Fixation Pathway Is Indirectly Activated by Light 740
Protein–Protein Interactions Mediated by an Intrinsically Unstructured Protein Also Regulate Calvin–Benson Cycle Activity 741
- 21.8 How Does Photorespiration Limit CO_2 Fixation? 741
Tropical Grasses Use the Hatch–Slack Pathway to Capture Carbon Dioxide for CO_2 Fixation 742
Cacti and Other Desert Plants Capture CO_2 at Night 744
Foundational Biochemistry 745
Problems 746
Further Reading 747

22

Gluconeogenesis, Glycogen Metabolism, and the Pentose Phosphate Pathway 751

- 22.1 What Is Gluconeogenesis, and How Does It Operate? 752
The Substrates for Gluconeogenesis Include Pyruvate, Lactate, and Amino Acids 752
Nearly All Gluconeogenesis Occurs in the Liver and Kidneys in Animals 752
- Human Biochemistry: The Chemistry of Glucose Monitoring Devices 752**
Gluconeogenesis Is Not Merely the Reverse of Glycolysis 753
Gluconeogenesis—Something Borrowed, Something New 753
Four Enzyme Reactions Are Unique to Gluconeogenesis 755
Human Biochemistry: Metformin—a Diabetes Drug with Multiple Actions 758
- 22.2 How Is Gluconeogenesis Regulated? 759
Critical Developments in Biochemistry: The Pioneering Studies of Carl and Gerty Cori 760
Gluconeogenesis Is Regulated by Allosteric and Substrate-Level Control Mechanisms 760
A Deeper Look: TIGAR—A p53-Induced Enzyme That Mimics Fructose-2,6-Bisphosphatase 762
Substrate Cycles Provide Metabolic Control Mechanisms 763
- 22.3 How Are Glycogen and Starch Catabolized in Animals? 764
Dietary Starch Breakdown Provides Metabolic Energy 764
Metabolism of Tissue Glycogen Is Regulated 765
- 22.4 How Is Glycogen Synthesized? 766
Glucose Units Are Activated for Transfer by Formation of Sugar Nucleotides 766
UDP–Glucose Synthesis Is Driven by Pyrophosphate Hydrolysis 766
Glycogen Synthase Catalyzes Formation of $\alpha(1 \rightarrow 4)$ Glycosidic Bonds in Glycogen 767
Glycogen Branching Occurs by Transfer of Terminal Chain Segments 768
- 22.5 How Is Glycogen Metabolism Controlled? 768
Glycogen Metabolism Is Highly Regulated 768
Human Biochemistry: Advanced Glycation End Products—A Serious Complication of Diabetes 769
Glycogen Synthase Is Regulated by Covalent Modification 770
Hormones Regulate Glycogen Synthesis and Degradation 772
Human Biochemistry: Carbohydrate Utilization in Exercise 772
Critical Developments in Biochemistry: O-GlcNAc Signaling and the Hexosamine Biosynthetic Pathway 775
- 22.6 How Does Glucose Provide Electrons for Biosynthesis? 776
The Pentose Phosphate Pathway Operates Mainly in Liver and Adipose Cells 776
The Pentose Phosphate Pathway Begins with Two Oxidative Steps 778
There Are Four Nonoxidative Reactions in the Pentose Phosphate Pathway 779
Human Biochemistry: Aldose Reductase and Diabetic Cataract Formation 780

Utilization of Glucose-6-P Depends on the Cell's Need for ATP, NADPH, and Ribose-5-P 783

Critical Developments in Biochemistry: Integrating the Warburg Effect—ATP Consumption Promotes Cancer Metabolism 785

Xylulose-5-Phosphate Is a Metabolic Regulator 786

Fatty Acid Catabolism 791

23.1 How Are Fats Mobilized from Dietary Intake and Adipose Tissue? 791

Modern Diets Are Often High in Fat 791

Triacylglycerols Are a Major Form of Stored Energy in Animals 792

Hormones Trigger the Release of Fatty Acids from Adipose Tissue 792

Degradation of Dietary Triacylglycerols Occurs Primarily in the Duodenum 792

Human Biochemistry: Serum Albumin—Tramp Steamer of the Bloodstream 795

A Deeper Look: The Biochemistry of Obesity 796

23.2 How Are Fatty Acids Broken Down? 797

Coenzyme A Activates Fatty Acids for Degradation 798

Carnitine Carries Fatty Acyl Groups Across the Inner Mitochondrial Membrane 799

β -Oxidation Involves a Repeated Sequence of Four Reactions 800

Repetition of the β -Oxidation Cycle Yields a Succession of Acetate Units 803

Human Biochemistry: Exercise Can Reverse the Consequences of Metabolic Syndrome 804

Complete β -Oxidation of One Palmitic Acid Yields 113.7 Molecules of ATP 805

Migratory Birds Travel Long Distances on Energy from Fatty Acid Oxidation 805

Fatty Acid Oxidation Is an Important Source of Metabolic Water for Some Animals 806

23.3 How Are Odd-Carbon Fatty Acids Oxidized? 807

β -Oxidation of Odd-Carbon Fatty Acids Yields Propionyl-CoA 807

A B_{12} -Catalyzed Rearrangement Yields Succinyl-CoA from L-Methylmalonyl-CoA 808

Net Oxidation of Succinyl-CoA Requires Conversion to Acetyl-CoA 808

A Deeper Look: The Activation of Vitamin B_{12} 808

23.4 How Are Unsaturated Fatty Acids Oxidized? 809

An Isomerase and a Reductase Facilitate the β -Oxidation of Unsaturated Fatty Acids 809

Degradation of Polyunsaturated Fatty Acids Requires 2,4-Dienoyl-CoA Reductase 809

A Deeper Look: Can Natural Antioxidants in Certain Foods Improve Fat Metabolism? 811

23.5 Are There Other Ways to Oxidize Fatty Acids? 811

Peroxisomal β -Oxidation Requires FAD-Dependent Acyl-CoA Oxidase 811

Branched-Chain Fatty Acids Are Degraded Via α -Oxidation 812

ω -Oxidation of Fatty Acids Yields Small Amounts of Dicarboxylic Acids 813

23.6 What Are Ketone Bodies, and What Role Do They Play in Metabolism? 813

Ketone Bodies Are a Significant Source of Fuel and Energy for Certain Tissues 813

Human Biochemistry: Large Amounts of Ketone Bodies Are Produced in Diabetes Mellitus 813

β -Hydroxybutyrate Is a Signaling Metabolite 815

Foundational Biochemistry 816

Problems 816

Further Reading 818

24

Lipid Biosynthesis 821

24.1 How Are Fatty Acids Synthesized? 821

Formation of Malonyl-CoA Activates Acetate Units for Fatty Acid Synthesis 822

Fatty Acid Biosynthesis Depends on the Reductive Power of NADPH 822

Cells Must Provide Cytosolic Acetyl-CoA and Reducing Power for Fatty Acid Synthesis 822

Acetate Units Are Committed to Fatty Acid Synthesis by Formation of Malonyl-CoA 824

Acetyl-CoA Carboxylase Is Biotin Dependent and Displays Ping-Pong Kinetics 824

Acetyl-CoA Carboxylase in Animals Is a Multifunctional Protein 824

Phosphorylation of ACC Modulates Activation by Citrate and Inhibition by Palmitoyl-CoA 826

Acyl Carrier Proteins Carry the Intermediates in Fatty Acid Synthesis 826

In Some Organisms, Fatty Acid Synthesis Takes Place in Multienzyme Complexes 827

Decarboxylation Drives the Condensation of Acetyl-CoA and Malonyl-CoA 827

Reduction of the β -Carbonyl Group Follows a Now-Familiar Route 829

Eukaryotes Build Fatty Acids on Megasynthase Complexes 830

C_{16} Fatty Acids May Undergo Elongation and Unsaturation 832

Unsaturation Reactions Occur in Eukaryotes in the Middle of an Aliphatic Chain 833

The Unsaturation Reaction May Be Followed by Chain Elongation 834

Mammals Cannot Synthesize Most Polyunsaturated Fatty Acids 834

Arachidonic Acid Is Synthesized from Linoleic Acid by Mammals 834

Regulatory Control of Fatty Acid Metabolism Is an Interplay of Allosteric Modifiers and Phosphorylation–Dephosphorylation Cycles 835

Hormonal Signals Regulate ACC and Fatty Acid Biosynthesis 835

Human Biochemistry: $\omega 3$ and $\omega 6$ —Essential Fatty Acids with Many Functions 836

24.2 How Are Complex Lipids Synthesized? 837

Glycerolipids Are Synthesized by Phosphorylation and Acylation of Glycerol 838

Eukaryotes Synthesize Glycerolipids from CDP-Diacylglycerol or Diacylglycerol 838

Human Biochemistry: Lipins—Phosphatases Essential for Triglyceride Synthesis and Other Functions 838

Phosphatidylethanolamine Is Synthesized from Diacylglycerol and CDP-Ethanolamine 841

Exchange of Ethanolamine for Serine Converts Phosphatidylethanolamine to Phosphatidylserine 841

Eukaryotes Synthesize Other Phospholipids Via CDP-Diacylglycerol 841

Dihydroxyacetone Phosphate Is a Precursor to the Plasmalogens 843

Platelet-Activating Factor Is Formed by Acetylation of 1-Alkyl-2-Lysophosphatidylcholine 844

Sphingolipid Biosynthesis Begins with Condensation of Serine and Palmitoyl-CoA 844

Ceramide Is the Precursor for Other Sphingolipids and Cerebrosides 844

24.3 How Are Eicosanoids Synthesized, and What Are Their Functions? 847

Eicosanoids Are Local Hormones 847

Prostaglandins Are Formed from Arachidonate by Oxidation and Cyclization 847

A Variety of Stimuli Trigger Arachidonate Release and Eicosanoid Synthesis 847

A Deeper Look: The Molecular Basis for the Action of Nonsteroidal Anti-inflammatory Drugs 849

24.4 How Is Cholesterol Synthesized? 851

Mevalonate Is Synthesized from Acetyl-CoA Via HMG-CoA Synthase 851

Why Can't Thiolase Be Used in Fatty Acid Synthesis? 851

Squalene Is Synthesized from Mevalonate 852

Human Biochemistry: Statins Lower Serum Cholesterol Levels 854

Conversion of Lanosterol to Cholesterol Requires 20 Additional Steps 856

24.5 How Are Lipids Transported Throughout the Body? 856

Lipoprotein Complexes Transport Triacylglycerols and Cholesterol Esters 856

Human Biochemistry: APOC3—An Apolipoprotein That Regulates Plasma Triglyceride Levels 857

Lipoproteins in Circulation Are Progressively Degraded by Lipoprotein Lipase 857

The Structure of the LDL Receptor Involves Five Domains 859

Defects in Lipoprotein Metabolism Can Lead to Elevated Serum Cholesterol 860

Human Biochemistry: New Cholesterol-Lowering Drugs Target PCSK9, an LDL Receptor Chaperone 861

24.6 How Are Bile Acids Biosynthesized? 861

Human Biochemistry: Niemann—Pick Type C Disease—A Hydrophobic Handoff Fumbled 862

Human Biochemistry: Steroid 5 α -Reductase—A Factor in Male Baldness, Prostatic Hyperplasia, and Prostate Cancer 863

24.7 How Are Steroid Hormones Synthesized and Utilized? 864

Pregnenolone and Progesterone Are the Precursors of All Other Steroid Hormones 864

Cortisol and Other Corticosteroids Regulate a Variety of Body Processes 864

Foundational Biochemistry 866

Problems 866

Further Reading 868

25

Nitrogen Acquisition and Amino Acid Metabolism 871

25.1 Which Metabolic Pathways Allow Organisms to Live on Inorganic Forms of Nitrogen? 871

Nitrogen Is Cycled between Organisms and the Inanimate Environment 872

Nitrate Assimilation Is the Principal Pathway for Ammonium Biosynthesis 872

Organisms Gain Access to Atmospheric N₂ via the Pathway of Nitrogen Fixation 874

25.2 What Is the Metabolic Fate of Ammonium? 877

The Citric Acid Cycle Intermediate α -Ketoglutarate Is Precursor to Both Glutamate and Glutamine 877

The Major Pathways of Ammonium Assimilation Lead to Glutamine Synthesis 879

25.3 What Regulatory Mechanisms Act on *Escherichia coli* Glutamine Synthetase? 880

Glutamine Synthetase Is Allosterically Regulated 880

Glutamine Synthetase Is Regulated by Covalent Modification 882

Glutamine Synthetase Is Regulated through Gene Expression 882

Glutamine in the Human Body 883

25.4 How Do Organisms Synthesize Amino Acids? 884

Human Biochemistry: Human Dietary Requirements for Amino Acids 885

Amino Acids Are Formed from α -Keto Acids by Transamination 886

A Deeper Look: The Mechanism of the Aminotransferase (Transamination) Reaction 886

The α -Ketoglutarate Family of Amino Acids Includes Glu, Gln, Pro, Arg, and Lys 887

The Urea Cycle Acts to Excrete Excess N through Arg Breakdown 889

A Deeper Look: The Urea Cycle as Both an Ammonium and a Bicarbonate Disposal Mechanism 891

The Oxaloacetate Family of Amino Acids Includes Asp, Asn, Lys, Met, Thr, and Ile 893

The Pyruvate Family of Amino Acids Includes Ala, Val, and Leu 897

The 3-Phosphoglycerate Family of Amino Acids Includes Ser, Gly, and Cys 897

The Aromatic Amino Acids Are Synthesized from Chorismate 902

A Deeper Look: Amino Acid Biosynthesis Inhibitors as Herbicides 906

Histidine Biosynthesis and Purine Biosynthesis Are Connected by Common Intermediates 907

25.5 How Does Amino Acid Catabolism Lead into Pathways of Energy Production? 909

The 20 Common Amino Acids Are Degraded by 20 Different Pathways That Converge to Just 7 Metabolic Intermediates 909

Human Biochemistry: Amino Acid Metabolism and Cancer 916

Animals Differ in the Form of Nitrogen That They Excrete 916

Human Biochemistry: Hereditary Defects in Phe Catabolism Underlie Alkaptonuria and Phenylketonuria 916

Foundational Biochemistry 917

Problems 918

Further Reading 919

26

Synthesis and Degradation of Nucleotides 921

26.1 How Do Cells Synthesize Nucleotides? 921

26.2 How Do Cells Synthesize Purines? 922

IMP Is the Immediate Precursor to GMP and AMP 922

A Deeper Look: Tetrahydrofolate and One-Carbon Units 924

Human Biochemistry: SAICAR Is a Key Signal for Metabolic Reprogramming in Cancer Cells 926

Human Biochemistry: Folate Analogs as Antimicrobial and Anticancer Agents 928

AMP and GMP Are Synthesized from IMP 928

The Purine Biosynthetic Pathway Is Regulated at Several Steps 929

ATP-Dependent Kinases Form Nucleoside Diphosphates and Triphosphates from the Nucleoside Monophosphates 930

26.3 Can Cells Salvage Purines? 931

26.4 How Are Purines Degraded? 931

Human Biochemistry: Lesch-Nyhan Syndrome—HGPRT Deficiency Leads to a Severe Clinical Disorder 932

The Major Pathways of Purine Catabolism Lead to Uric Acid 932

Human Biochemistry: Severe Combined Immunodeficiency Syndrome—A Lack of Adenosine Deaminase Is One Cause of This Inherited Disease 933

The Purine Nucleoside Cycle in Skeletal Muscle Serves as an Anaplerotic Pathway 933

Xanthine Oxidase 933

Gout Is a Disease Caused by an Excess of Uric Acid 934

Different Animals Oxidize Uric Acid to Form Various Excretory Products 935

26.5 How Do Cells Synthesize Pyrimidines? 935

The Pyrimidine Biosynthetic Pathway from Carbamoyl-P and Aspartate to UMP 936

UMP Synthesis Leads to Formation of the Two Most Prominent Ribonucleotides—UTP and CTP 936

Pyrimidine Biosynthesis Is Regulated at ATCase in Bacteria and at CPS-II in Animals 938

“Metabolic Channeling” by Multifunctional Enzymes of Mammalian Pyrimidine Biosynthesis 939

26.6 How Are Pyrimidines Degraded? 939

26.7 How Do Cells Form the Deoxyribonucleotides That Are Necessary for DNA Synthesis? 940

E. coli Ribonucleotide Reductase Has Three Different Nucleotide-Binding Sites 940

Thioredoxin Provides the Reducing Power for Ribonucleotide Reductase 941

Both the Specificity and the Catalytic Activity of Ribonucleotide Reductase Are Regulated by Nucleotide Binding 942

26.8 How Are Thymine Nucleotides Synthesized? 943

Human Biochemistry: Fluoro-Substituted Pyrimidines in Cancer Chemotherapy, Fungal Infections, and Malaria 944

A Deeper Look: Fluoro-Substituted Analogs Are Good Trojan Horse Inhibitors 945

Foundational Biochemistry 945

DNA Metabolism: Replication, Recombination, and Repair 981

- DNA Metabolism 981
- 28.1 **How Is DNA Replicated? 982**
 - DNA Replication Is Bidirectional 982
 - Replication Requires Unwinding of the DNA Helix 982
 - DNA Replication Is Semidiscontinuous 983
 - The Biochemical Evidence for Semidiscontinuous DNA Replication 984
 - Initiation of DNA Replication 985
- 28.2 **What Are the Functions of DNA Polymerases? 985**
 - Biochemical Characterization of DNA Polymerases 985
 - E. coli* Cells Have Several Different DNA Polymerases 986
 - E. coli* DNA Polymerase III Holoenzyme Replicates the *E. coli* Chromosome 986
 - A DNA Polymerase III Holoenzyme Sits at Each Replication Fork 988
 - DNA Polymerase I Removes the RNA Primers and Fills in the Gaps 989
 - DNA Polymerase I Also Plays a Role in DNA Double-Strand Break Repair 989
 - DNA Ligase Seals the Nicks Between Okazaki Fragments 990
 - DNA Polymerase Is Its Own Proofreader 990
 - DNA Replication Terminates at the *Ter* Region 990
 - A Deeper Look: A Mechanism for All Polymerases 990**
 - DNA Polymerases Are Immobilized in Replication Factories 991
- 28.3 **Why Are There So Many DNA Polymerases? 991**
 - Cells Have Different Versions of DNA Polymerase, Each for a Particular Purpose 991
 - The Common Architecture of DNA Polymerases 991
- 28.4 **How Is DNA Replicated in Eukaryotic Cells? 992**
 - The Cell Cycle Controls the Timing of DNA Replication 992
 - Proteins of the Prereplication Complex Are AAA+ ATPase Family Members 995
 - Geminin Provides Another Control Over Replication Initiation 995

Eukaryotic Cells Also Contain a Number of Different DNA Polymerases 995

28.5 How Are the Ends of Chromosomes Replicated? 996

28.6 How Are RNA Genomes Replicated? 996

A Deeper Look: RNA as Genetic Material 998

The Enzymatic Activities of Reverse Transcriptases 998

28.7 How Is the Genetic Information Rearranged by Genetic Recombination? 999

General Recombination Requires Breakage and Reunion of DNA Strands 999

Homologous Recombination Proceeds According to the Holliday Model 1000

The Enzymes of General Recombination Include RecA, RecBCD, RuvA, RuvB, and RuvC 1000

The RecBCD Enzyme Complex Unwinds dsDNA and Cleaves Its Single Strands 1002

The RecA Protein Can Bind ssDNA and Then Interact with Duplex DNA 1002

RuvA, RuvB, and RuvC Proteins Resolve the Holliday Junction to Form the Recombination Products 1004

The Three Rs of Genomic Manipulation: Replication, Recombination, and Repair 1005

A Deeper Look: Knockout Mice: A Method to Investigate the Biological Role of a Gene 1006

Homologous Recombination in Eukaryotes Helps to Prevent Cancer 1007

Transposons Are DNA Sequences That Can Move from Place to Place in the Genome 1007

Human Biochemistry: The Breast Cancer Susceptibility Genes BRCA1 and BRCA2 Are Involved in DNA Damage Control and DNA Repair 1008

28.8 Can DNA Be Repaired? 1008

Double-Strand DNA Breaks 1009

Mismatch Repair Corrects Errors Introduced During DNA Replication 1012

Damage to DNA by UV Light or Chemical Modification Can Also Be Repaired 1012

A Deeper Look: Transgenic Animals Are Animals Carrying Foreign Genes 1013

28.9 What Is the Molecular Basis of Mutation? 1014

Point Mutations Arise by Inappropriate Base-Pairing 1015

Mutations Can Be Induced by Base Analogs 1016

Chemical Mutagens React with the Bases in DNA 1016

Insertions and Deletions 1016

28.10 Can Genetic Recombination Create Protein Diversity? 1018

Cells Active in the Immune Response Are Capable of Gene Rearrangement 1018

Immunoglobulin G Molecules Contain Regions of Variable Amino Acid Sequence 1018

The Immunoglobulin Genes Undergo Gene Rearrangement 1019

DNA Rearrangements Assemble an L-Chain Gene by Combining Three Separate Genes 1021

DNA Rearrangements Assemble an H-Chain Gene by Combining Four Separate Genes 1021

V–J and V–D–J Joining in Light- and Heavy-Chain Gene Assembly Is Mediated by the RAG Proteins 1022

Imprecise Joining of Immunoglobulin Genes Creates New Coding Arrangements 1025

Antibody Diversity Is Due to Immunoglobulin Gene Rearrangements 1025

Foundational Biochemistry 1026

Problems 1027

Further Reading 1028

29

Transcription and the Regulation of Gene Expression 1033

29.1 How Are Genes Transcribed in Bacteria? 1033

A Deeper Look: Conventions Used in Expressing the Sequences of Nucleic Acids and Proteins 1034

Bacterial RNA Polymerases Use Their Sigma Subunits to Identify Sites Where Transcription Begins 1034

The Process of Transcription Has Four Stages 1034

A Deeper Look: DNA Footprinting—Identifying the Nucleotide Sequence in DNA Where a Protein Binds 1037

29.2 How Is Transcription Regulated in Bacteria? 1041

Transcription of Operons Is Controlled by Induction and Repression 1041

The *lac* Operon Is a Paradigm of Operons 1042

lac Repressor Is a Negative Regulator of the *lac* Operon 1043

CAP Is a Positive Regulator of the *lac* Operon 1044

A Deeper Look: Quantitative Evaluation of *lac* Repressor: DNA Interactions 1045

Negative and Positive Control Systems Are Fundamentally Different 1046

The *araBAD* Operon Is Both Positively and Negatively Controlled by *AraC* 1046

The *trp* Operon Is Regulated Through a Co-Repressor–Mediated Negative Control Circuit 1048

Attenuation Is a Prokaryotic Mechanism for Post-Transcriptional Regulation of Gene Expression 1049

DNA: Protein Interactions and Protein:Protein Interactions Are Essential to Transcription Regulation 1050

Proteins That Activate Transcription Work Through Protein:Protein Contacts with RNA Polymerase 1050

DNA Looping Allows Multiple DNA-Binding Proteins to Interact with One Another 1051

29.3 How Are Genes Transcribed in Eukaryotes? 1052

Eukaryotes Have Three Classes of RNA Polymerases 1053

RNA Polymerase II Transcribes Protein-Coding Genes 1053

The Regulation of Gene Expression Is More Complex in Eukaryotes 1055

Gene Regulatory Sequences in Eukaryotes Include Promoters, Enhancers, Insulators, and Silencers 1055

Transcription Initiation by RNA Polymerase II Requires TBP and the GTFs 1057

The Role of Mediator in Transcription Activation and Repression 1058

Mediator as a Repressor of Transcription 1060

Chromatin-Remodeling Complexes and Histone-Modifying Enzymes Alleviate the Repression Due to Nucleosomes 1060

Chromatin-Remodeling Complexes Are Nucleic Acid–Stimulated Multisubunit ATPases 1061

Covalent Modification of Histones 1061

Covalent Modification of Histones Suggests the Existence of a Histone Code 1062

Methylation and Phosphorylation Act as a Binary Switch that Regulates Chromatin Dynamics 1062

Chromatin Deacetylation Leads to Transcription Repression 1063

Nucleosome Alteration and Interaction of RNA Polymerase II with the Promoter Are Essential Features in Eukaryotic Gene Activation 1063

29.4 How Do Gene Regulatory Proteins Recognize Specific DNA Sequences? 1064

Human Biochemistry: Storage of Long-Term Memory Depends on Gene Expression Activated by CREB-Type Transcription Factors 1065

α -Helices Fit Snugly into the Major Groove of B-DNA 1065

Proteins with the Helix-Turn-Helix Motif Use One Helix to Recognize DNA 1065

Some Proteins Bind to DNA via Zn-Finger Motifs 1066

Some DNA-Binding Proteins Use a Basic Region-Leucine Zipper (*bZIP*) Motif 1067

29.5 How Are Eukaryotic Transcripts Processed and Delivered to the Ribosomes for Translation? 1068

Eukaryotic Genes Are Split Genes 1068

The Organization of Exons and Introns in Split Genes Is Both Diverse and Conserved 1069

Post-Transcriptional Processing of Messenger RNA Precursors Involves Capping, Methylation, Polyadenylation, and Splicing 1069

Nuclear Pre-mRNA Splicing 1072

The Splicing Reaction Proceeds via Formation of a Lariat Intermediate 1072

Splicing Depends on snRNPs 1073

snRNPs Form the Spliceosome 1073

Alternative RNA Splicing Creates Protein Isoforms 1074

A Deeper Look: Inteins—Bizarre Parasitic Genetic Elements Encoding a Protein-Splicing Activity 1075

RNA Editing: Another Mechanism That Increases the Diversity of Genomic Information 1076

29.6 Can Gene Expression Be Regulated Once the Transcript Has Been Synthesized? 1077

miRNAs Are Key Regulators in Post-Transcriptional Gene Regulation 1077

Targeted RNA Degradation by Exosomes 1079

29.7 Can We Propose a Unified Theory of Gene Expression? 1080

Foundational Biochemistry 1081

Problems 1082

Further Reading 1084

30

Protein Synthesis 1089

30.1 What Is the Genetic Code? 1090

The Genetic Code Is a Triplet Code 1090

Codons Specify Amino Acids 1090

A Deeper Look: Natural and Unnatural Variations in the Standard Genetic Code 1092

30.2 How Is an Amino Acid Matched with Its Proper tRNA? 1092

Aminoacyl-tRNA Synthetases Interpret the Second Genetic Code 1093

Evolution Has Provided Two Distinct Classes of Aminoacyl-tRNA Synthetases 1093

Aminoacyl-tRNA Synthetases Can Discriminate Between the Various tRNAs 1095

Escherichia coli Glutaminyl-tRNA^{Gln} Synthetase Recognizes Specific Sites on tRNA^{Gln} 1096

The Identity Elements Recognized by Some Aminoacyl-tRNA Synthetases Reside in the Anticodon 1097

A Single G:U Base Pair Defines tRNA^{Ala}s 1097

30.3 What Are the Rules in Codon–Anticodon Pairing? 1098

Francis Crick Proposed the Wobble Hypothesis for Codon–Anticodon Pairing 1098

Some Codons Are Used More Than Others 1098

Nonsense Suppression Occurs When Suppressor tRNAs Read Nonsense Codons 1100

30.4 What Is the Structure of Ribosomes, and How Are They Assembled? 1100

Prokaryotic Ribosomes Are Composed of 30S and 50S Subunits 1100

Ribosomes Spontaneously Self-Assemble In Vitro 1102

Ribosomes Have a Characteristic Anatomy 1102

The Cytosolic Ribosomes of Eukaryotes Are Larger Than Prokaryotic Ribosomes 1103

30.5 What Are the Mechanics of mRNA Translation? 1104

Translation Can be Organized into Three Steps: Initiation, Elongation, and Termination 1104

Peptide Chain Initiation in Bacteria Requires a G-Protein Family Member 1105

Peptide Chain Elongation Requires Two G-Protein Family Members 1107

The Elongation Cycle 1107

Aminoacyl-tRNA Binding and the Peptidyl Transferase Reaction 1108

GTP Hydrolysis Fuels the Conformational Changes That Drive Ribosomal Functions 1112

A Deeper Look: Molecular Mimicry—The Structures of EF-Tu: Aminoacyl-tRNA, EF-G, and RF-3 1112

Peptide Chain Termination Requires Yet Another G-Protein Family Member 1113

The Ribosomal Subunits Cycle Between 70S Complexes and a Pool of Free Subunits 1113

A Deeper Look: Tethered Ribosomes Open New Possibilities in Synthetic Biology 1115

Polyribosomes Are the Active Structures of Protein Synthesis 1116

30.6 How Are Proteins Synthesized in Eukaryotic Cells? 1116

Peptide Chain Initiation in Eukaryotes 1116

Control of Eukaryotic Peptide Chain Initiation Is One Mechanism for Post-Transcriptional Regulation of Gene Expression 1118

Peptide Chain Elongation in Eukaryotes Resembles the Prokaryotic Process 1120

Human Biochemistry: Diphtheria Toxin ADP-Ribosylates eEF₂ 1120

Eukaryotic Peptide Chain Termination Requires eRF1, eRF3, and GTP 1121

30.7 Do Protein Synthesis Inhibitors Have Clinical Applications? 1121

The Decoding Site Is a Target of Aminoglycoside Antibiotics 1121

Many Antibiotics Target the PTC and the Peptide Exit Tunnel 1122

Eukaryotic-Specific Protein Synthesis Inhibitors 1124

Foundational Biochemistry 1124

Problems 1125

32

The Reception and Transmission of Extracellular Information 1161

32.1 What Are Hormones? 1163

Steroid Hormones Act in the Nucleus or at the Plasma Membrane 1163

Polypeptide Hormones Share Similarities of Synthesis and Processing 1163

32.2 What Is Signal Transduction? 1164

Many Signaling Pathways Involve Enzyme Cascades 1165

Signaling Pathways Connect Membrane Interactions with Events in the Nucleus 1165

Signaling Pathways Depend on Multiple Molecular Interactions 1165

32.3 How Do Signal-Transducing Receptors Respond to the Hormonal Message? 1168

The G-Protein–Coupled Receptors Are 7-TMS Integral Membrane Proteins 1168

The Single TMS Receptors Are Guanylyl Cyclases or Tyrosine Kinases 1170

RTKs and RGCs Are Membrane-Associated Allosteric Enzymes 1170

The EGF Receptor Is Activated by Ligand-Induced Dimerization 1170

The Insulin Receptor Mediates Several Signaling Pathways 1173

Receptor Guanylyl Cyclases Mediate Effects of Natriuretic Hormones 1175

Nonreceptor Tyrosine Kinases Are Typified by pp60^{src} 1177

A Deeper Look: Nitric Oxide, Nitroglycerin, and Alfred Nobel 1178

Soluble Guanylyl Cyclases Are Receptors for Nitric Oxide 1179

32.4 How Are Receptor Signals Transduced? 1179

GPCR Signals Are Transduced by G Proteins 1179

Cyclic AMP Is a Second Messenger 1180

Ras and Other Small GTP-Binding Proteins Are Proto-Oncogene Products 1181

G Proteins Are Universal Signal Transducers 1182

Specific Phospholipases Release Second Messengers 1183

Human Biochemistry: Cancer, Oncogenes, and Tumor Suppressor Genes 1185

Lipids Such as Phosphatidylcholine, Sphingomyelin, Glycosphingolipids, and Arachidonic Acid Also Generate Second Messengers 1185

Calcium Is a Second Messenger 1186

Calmodulin Target Proteins Possess a Basic Amphiphilic Helix 1186

Human Biochemistry: PI Metabolism and the Pharmacology of Li⁺ 1186

32.5 How Do Effectors Convert the Signals to Actions in the Cell? 1188

Protein Kinase A Is a Paradigm of Kinases 1188

A Deeper Look: Mitogen-Activated Protein Kinases and Phosphorelay Systems 1189

Protein Kinase C Is a Family of Isozymes 1189

Protein Tyrosine Kinase pp60^{c-src} Is Regulated by Phosphorylation/Dephosphorylation 1190

Protein Tyrosine Phosphatase SHP-2 Is a Nonreceptor Tyrosine Phosphatase 1190

32.6 How Are Signaling Pathways Organized and Integrated? 1191

GPCRs Can Signal Through G-Protein–Independent Pathways 1191

G-Protein Signaling Is Modulated by RGS/GAPs 1192

GPCR Desensitization Leads to New Signaling Pathways 1192

A Deeper Look: Whimsical Names for Proteins and Genes 1196

Receptor Responses Can Be Coordinated by Transactivation 1196

Signals from Multiple Pathways Can Be Integrated 1196

32.7 How Do Neurotransmission Pathways Control the Function of Sensory Systems? 1198

Nerve Impulses Are Carried by Neurons 1198

Ion Gradients Are the Source of Electrical Potentials in Neurons 1198

Action Potentials Carry the Neural Message 1199

The Action Potential Is Mediated by the Flow of Na⁺ and K⁺ Ions 1200

Neurons Communicate at the Synapse 1201

Communication at Cholinergic Synapses Depends upon Acetylcholine 1202

There Are Two Classes of Acetylcholine Receptors 1202

Amino Acids, Catecholamines, and Peptides Can Act as Neurotransmitters within Synaptic Junctions 1204

Glutamate and Aspartate Are Excitatory Amino Acid Neurotransmitters 1205

A Deeper Look: Tetrodotoxin and Saxitoxin Are Na⁺ Channel Toxins 1206

Human Biochemistry: Neurexins and Neuroligins—the Scaffolding of Learning and Memory 1207

γ-Aminobutyric Acid and Glycine Are Inhibitory Neurotransmitters 1208

Human Biochemistry: The Biochemistry of Neurological Disorders 1210

The Catecholamine Neurotransmitters Are Derived from Tyrosine 1212

Various Peptides Also Act as Neurotransmitters 1212

Some Ion Channels Respond to Physical Stimuli Rather Than Chemicals 1213

Foundational Biochemistry 1214

Careers in Chemistry

- Chapter 1: **Michelle Nguyen**, Compliance and Integrity Officer at Nationwide Children's Hospital 9
- Chapter 2: **Kilan C. Ashad-Bishop**, Biomedical Scientist and Advocate at Sylvester Comprehensive Cancer Center 32
- Chapter 3: (Chemistry in History) **Satoshi Ōmura**, 2015 Nobel Prize Winner in Physiology or Medicine for his studies on novel therapies against infections caused by roundworm parasites 53
- Chapter 4: **Vanessa A. Nadal**, Professor of Law at Fordham University and co-creator of first U.S. Cosmetics Regulation course 78
- Chapter 5: **Lilla Morton**, Biochemistry Teacher at Zayed Private Academy 106
- Chapter 6: (Chemistry in History) **César Milstein**, 1984 Nobel Prize Winner for Physiology or Medicine for his studies on monoclonal antibodies 147
- Chapter 7: **Dr. Shannon Timmons**, Professor and Chair of the Natural Sciences Department at Lawrence Technological University 194
- Chapter 8: (Chemistry in History) **Alice Ball**, creator of the "Ball Method" as a treatment for leprosy in the early 20th century 240
- Chapter 9: **Dr. Audie Thompson**, Assistant Professor of Chemical Engineering at the University of Arkansas 267
- Chapter 10: **Phillip Nega**, researcher in solid-state battery technology at A123 Systems 325
- Chapter 11: **Sabrina Farais**, lab director with the Oklahoma Medical Marijuana Authority (OMMA) 348
- Chapter 12: (Chemistry in History) **Tu Youyou**, 2015 Nobel Prize winner in Physiology or Medicine for her discoveries of novel therapies against malaria 394
- Chapter 13: (Chemistry in History) **Maud Menten**, co-creator of the Michaelis-Menten equation which relates the rate of an enzyme-catalyzed reaction to the enzyme's affinity for its substrate 434
- Chapter 14: (Chemistry in History) **Dr. John Cornforth**, 1975 Nobel Prize Winner in Chemistry for his studies of the stereochemistry of enzymes involved in cholesterol biosynthesis 483
- Chapter 15: **Dr. Cierra Smith**, Manager of Diversity, Equity, and Inclusion (DEI) Programs for the American Society of Biochemistry and Molecular Biology (ASBMB) 512
- Chapter 16: **Dr. Enrique M. De La Cruz**, Professor and Chair of Molecular Biophysics and Biochemistry at Yale University 548
- Chapter 17: (Chemistry in History) **Dr. Marie Maynard Daly**, responsible for the earliest research on the relationship between diet, blood cholesterol, and heart health 580
- Chapter 18: **Neem J. Patel**, Ph.D. candidate at the University of California studying soil recovery after forest fires. 606
- Chapter 19: **Rochelle Diamond**, Manager of the Flow Cytometry/Cell Sorting Facility at the California Institute of Technology and founder of Out to Innovate 637
- Chapter 20: **Dr. Vincent Wu**, research scientist at Triplebar engineering fungi to produce bovine milk proteins 674
- Chapter 21: (Chemistry in History) **Dr. Emmett Chapelle**, inventor of method for the detection of ATP used today for detection of microbes in food and water 720
- Chapter 22: **Dr. Kayunta Johnson-Winters**, Associate Professor at the University of Texas at Arlington with research focused on F₄₂₀-dependent enzymes. 753
- Chapter 23: **Dr. Katherine Scheibel**, subject matter expert for Cengage Academic Publishing
- Chapter 24: (Chemistry in History) **Dr. Konard Emil Bloch**, 1964 Nobel Prize winner in Physiology or Medicine for his studies of cholesterol and fatty acid metabolism
- Chapter 25: **Dr. Squire J. Booker**, Evan Pugh Professor of Chemistry, Biochemistry, and Molecular Biology as well as the Eberly Distinguished Chair in Science at Pennsylvania State University 876
- Chapter 26: **Dr. Allison C. Augustus-Wallace**, Associate Professor and Director of Undergraduate Academic Pathway Programs for Diversity at LSU Health Sciences Center-New Orleans 927
- Chapter 27: **Dr. James M. Ntambi**, Professor at the University of Wisconsin-Madison and winner of the American Society for Biochemistry and Molecular Biology Award for Exemplary Contributions to Education

- Chapter 28: (Chemistry in History) **Dr. Slayton A. Evans, Jr.**, First African-American Assistant Professor of Chemistry at University of North Carolina-Chapel Hill and committee chair for the American Chemistry Society, the National Institutes of Health, and the National Science Foundation 983
- Chapter 29: **Dr. Elsa Pao**, Optometrist with her own private practice 1038
- Chapter 30: **Dr. Alison Brown**, Program Director for the National Institutes of Health's National Heart, Blood, and Lung Institute 1091
- Chapter 31: **Dr. Odutayo (Tayo) Odunuga**, Professor of Biochemistry at Stephen F. Austin State University 1135
- Chapter 32: **Dr. Shantá D. Hinton**, Associate Professor and Chair of Biology at the College of William and Mary 1164

PSAFE (Protein Structure and Function Exploration)

A Resource for Biochemistry Students and Instructors

The Protein Structure and Function Exploration (PSAFE) project* <http://psafeonline.net> at the University of Virginia was created as a semester-long project for biochemistry students to explore structure–function relationships in macromolecules and to research and write about their findings. Students doing the PSAFE project use the molecular-document capability of the ICM Browser (from Molsoft LLC) to accomplish their goals. In this exercise, each student progresses through tutorials about the basics of biomolecular structure to individual in-depth analysis of a chosen macromolecule and how it achieves its function. The project culminates in each student creating an interactive graphical display and accompanying narrative describing the chosen macromolecule’s structure-function relationships, together with relevant references. These student creations are reviewed and edited before posting to an archival website (<http://psafeonline.net>). The PSAFE archive contains descriptions of well over 1300 different proteins and nucleic acids and is available to anyone with an interest in exploring structure-function relationships in *macromolecules*. This semester-long research and writing project has been added to the Biochemistry 7e, online course to provide students with the opportunity to explore the structure and function of an assigned protein. The project culminates in the composition of an interactive narrative describing the macromolecule’s structure and function.

*Magnotti, E., Moy, J., Sleppy, R., Carey, A., Firdyiwiek, Y., Garrett, R. H., and Grisham, C., 2019. “Developing and Implementing a Free Online Protein Structure and Function Exploration Project to Teach Undergraduate Students Macromolecular Structure–Function Relationships.” *Journal of Chemical Education* **96**:729–733.

Laboratory Techniques in Biochemistry

All of our knowledge of biochemistry is the outcome of experiments. For the most part, this text presents biochemical knowledge as established fact, but students should never lose sight of the obligatory connection between scientific knowledge and its validation by observation and analysis. The path of discovery by experimental research is often indirect, tortuous, and confounding before the truth is realized. Laboratory techniques lie at the heart of scientific inquiry, and many techniques of biochemistry are presented within these pages to foster a deeper understanding of the biochemical principles and concepts that they reveal.

Recombinant DNA Techniques

Restriction endonuclease digestion of DNA *Section 10.6d*
Restriction mapping *Section 10.6e–f*
DNA sequencing *Section 11.1*
Nucleic acid hybridization *Section 11.3*
Chemical synthesis of nucleic acids *Section 11.6*
Cloning: recombinant DNA constructions *Section 12.1*
Construction of genomic DNA libraries *Section 12.2*
Combinatorial libraries of synthetic oligomers *Section 12.2*
Screening DNA libraries by colony hybridization *Section 12.2b*
PCR (polymerase chain reaction) *Section 12.2d*
mRNA isolation *Section 12.2e*
Construction of cDNA libraries *Section 12.2e*
Expressed sequence tags (ESTs) *Section 12.2e*
Southern blotting *Section 12.2d*
Gene chips (DNA microarrays) *Section 12.2f*
Protein expression from cDNA inserts *Section 12.3*
Screening protein expression libraries with antibodies *Section 12.3a*
Two-hybrid systems to identify protein-protein interactions *Section 12.3c*
Reporter gene constructs *Section 12.3b*
RT-qPCR (real-time quantitative PCR) *Section 12.3a*
In vitro mutagenesis *Section 12.3d*
ChIP-Seq (chromatin immunoprecipitation-DNA sequencing) *Section 12.3c*
RNAi *Section 12.4*
Genome editing with CRISPR-Cas9 *Section 12.5d*
Base editing with CRISPR-Cas9 *Section 12.5e*
Prime editing with CRISPR-Cas9 *Section 12.5f*
Gene silencing with CRISPR-Cas9 *Section 12.5g*
High-throughput screening *Section 12.6*
BioBricks *Section 12.7a*
CRISPR/Cas9 *Section 12.5*

Probing the Function of Biomolecules

Green fluorescent protein *Section 4.4*
Plotting enzyme kinetic data *Section 13.3j*
Enzyme inhibition *Section 13.4*
Isotopic tracers as molecular probes *Section 17.4c*
RNAi *Section 12.4*
NMR spectroscopy *Section 17.4d*
Transgenic animals *Section 28.8*
DNA footprinting *Section 29.1*

Techniques Relevant to Clinical Biochemistry

Human gene therapy *Section 12.5*
Metabolomic analysis *Section 17.5*

Fluxomics *Section 17.5*

Tumor diagnosis with positron emission tomography (PET) *Section 18.7*
Glucose monitoring devices *Section 22.1*
Fluoro-substituted analogs as therapeutic agents *Section 26.8*
“Knockout” mice *Section 28.7*

Isolation/Purification of Macromolecules

Ion exchange chromatography *Section 5.2*
Protein purification protocols *Section 5.2*
Dialysis and ultrafiltration *Section 5.2*
Size exclusion chromatography *Section 5.2*
SDS-polyacrylamide gel electrophoresis *Section 5.2*
Isoelectric focusing *Section 5.2*
Two-dimensional gel electrophoresis *Section 5.2*
Hydrophobic interaction chromatography *Section 5.2*
High-performance liquid chromatography *Section 5.2*
Affinity chromatography *Section 5.2*
Ultracentrifugation *Section 5.2*
Fractionation of cell extracts by centrifugation *Section 5.2*
Proteomic analysis by multidimensional protein identification technology *Section 5.8b*

Analyzing the Physical and Chemical Properties of Biomolecules

Titration of weak acids *Section 2.2b*
Preparation of buffers *Section 2.3*
Measurement of standard reduction potentials *Section 3.6*
Edman degradation *Section 4.3*
Nuclear magnetic resonance (NMR) *Sections 4.5 and 6.4*
Estimation of protein concentration *Section 5.2*
Amino acid analysis *Section 4.6*
Amino acid sequence determination *Section 5.3*
Mass spectrometry of proteins *Section 5.3i*
Solid-phase peptide synthesis *Section 5.5*
Cryo-Electron Microscopy *Section 6.4*
Membrane lipid phase transitions *Section 9.4b*
Nucleic acid hydrolysis *Section 10.6*
DNA sequencing *Section 11.1*
Single-molecule DNA sequencing *Section 11.1e,f*
Density gradient (isopycnic) centrifugation *Section 11.3*

Preface

Biochemistry

Scientific understanding of the molecular nature of life is growing at an astounding rate. Significantly, society is the prime beneficiary of this increased understanding. Cures for diseases, better public health, remedies for environmental pollution, and the development of cheaper and safer natural products are just a few practical benefits of this knowledge. In addition, this expansion of information fuels, in the words of Thomas Jefferson, “the illimitable freedom of the human mind.” Scientists can use the tools of biochemistry and molecular biology to explore all aspects of an organism—from basic questions about its chemical composition, through inquiries into the complexities of its metabolism, differentiation, and development, to analysis of its evolution, and even its behavior. New procedures based on the results of these explorations lie at the heart of the many modern medical miracles. Biochemistry is a science whose boundaries now encompass all aspects of biology, from molecules to cells, to organisms, to ecology, and to all aspects of health care. This seventh edition of *Biochemistry* embodies and reflects the expanse of this knowledge. We hope that this new edition will encourage students to ask questions of their own and to push the boundaries of their curiosity about science.

Making Connections

As the explication of natural phenomena rests more and more on biochemistry, its inclusion in undergraduate and graduate curricula in biology, chemistry, and the health sciences becomes imperative. The challenge to authors and instructors is a formidable one: how to familiarize students with the essential features of modern biochemistry in an introductory course or textbook. Fortunately, the increased scope of knowledge allows scientists to make generalizations connecting the biochemical properties of living systems with the character of their constituent molecules. As a consequence, these generalizations, validated by numerous examples, emerge in time as principles of biochemistry, principles that are useful in discerning and describing new relationships between diverse biomolecular functions and in predicting the mechanisms underlying newly discovered biomolecular processes. Nevertheless, it is increasingly apparent that students must develop skills in inquiry-based learning, so that beyond this first encounter with biochemical principles and concepts students are equipped to explore science on their own. Much of the design of this new edition is meant to foster the development of such skills.

We are both biochemists, but one of us spent his career in a biology department, and the other in a chemistry department. Undoubtedly, we each view biochemistry through the lens of our respective disciplines. We believe, however, that our collaboration on this textbook represents a melding of our perspectives that will provide new dimensions of appreciation and understanding for all students.

Our Audience

This biochemistry textbook is designed to communicate the fundamental principles upon which all life is based to students encountering biochemistry for the first time. We aim to bring an appreciation of biochemistry to a broad audience that includes undergraduates majoring in the life sciences, physical sciences, or premedical programs as well as medical students and graduate students in the various health sciences for whom biochemistry is an important route to understanding human physiology. To make this subject matter more relevant and interesting to all readers, we emphasize, where appropriate, the biochemistry of humans.

Objectives and Building on Previous Editions

We carry forward the clarity of purpose found in previous editions; namely, to illuminate for students the principles governing the structure, function, and interactions of biological molecules. At the same time, this new edition has been revised to reflect tremendous developments in biochemistry. Significantly, emphasis is placed on the interrelationships of ideas so that students can begin to appreciate the overarching questions of biochemistry.

New Features

New Textbook Features

- **Think-Pair-Share Problems** in every chapter encourage students to work collaboratively to further their understanding of biochemistry concepts.
- **Careers in Chemistry** showcase various career paths that students can take after studying biochemistry. By seeing a diverse, inclusive, and equitable chemical community, all students know that they have a future in chemistry-related careers.
- **Over 160 New and Revised Exercises** were added to the book and online course to keep the content current.
- **Step-by-Step Solutions** were added to examples to help students master the approach to complicated problems.
- **Recent Developments in Biochemistry:** A number of *Deeper Look* and *Critical Developments in Biochemistry* boxes were added to address the latest developments in biochemistry such as the human proteome, NMR and Cryo-EM, AlfaFold, and CRISPR-Cas9.

New to the Online Course and Resources

- **MCAT Essays and Practice Problems** accompanied by detailed answer explanations, written by members of medical school admissions and advisors, have been added to the online course in OWLv2 to prepare students for the biochemistry section of the MCAT exam.
- **Hints and Targeted Feedback.** Over fifty percent of problems in OWLv2 now come with targeted feedback on common errors that students make. The targeted feedback explains why the student's answer is incorrect and guides them toward a correct solution.
- **Laddered Assessments.** Conceptual mastery modules are combined with more traditional homework questions into one structured learning path, organized by topic at the chapter level.
- **Over 300 New Problems** were added to the online course.
- **PSAFE: Protein Structure and Function Exploration Project.** Students research a protein and use protein-modeling software to practice biochemistry actively in this research and writing semester-long project.
- **Protein Structure and Function Exploration Library of Proteins and Nucleic Acids** is an online resource (<http://www.psafeonline.net/>) of over 1300 protein and nucleic acid animations and interactive views, sorted by proteins and chapters in this textbook.

New to this Edition

Chapter 3 A new Deeper Look box called “Why Nature Chose Phosphates.”

Chapter 4 A new Deeper Look box called “Why Nature Chose Selenium,” and a revised Critical Developments in Biochemistry box on the incorporation of unnatural amino acids into proteins.

Chapter 5 A new exercise on determining amino-acid sequence from mass spectrometry data. Efforts to describe the human proteome are introduced in a new Deeper Look box: “The Human Proteome Project and the Human Protein Atlas.”

Chapter 6 A new Critical Developments in Biochemistry box on the X-ray crystallography of proteins and a revised Deeper Look feature on metamorphic proteins, which exist as an ensemble of structures of similar energies and stabilities. New Critical Developments in Biochemistry boxes on the Protein Data Bank (PDB) and “NMR and Cryo-EM — Revolutionary Methods that Probe Protein Structure and Dynamics” (including cryo-EM structure of the 2P spike protein mutant related to development of COVID-19 vaccines). New coverage of AlphaFold, artificial intelligence software that accurately predicts the three-dimensional structures of proteins based solely on their amino acid sequences.

Chapter 8 A new Human Biochemistry box on the development of vaccines for COVID-19 that employ lipid nanoparticles and make RNA vaccines practical and effective.

Chapter 9 New coverage of monotopic, bitopic, and polytopic membrane proteins and a section called “Dynamic Exchange of Lipids and Proteins with Membrane Domains.”

Chapter 10 An updated introduction to the many roles of small RNAs in the regulation of gene expression: miRNAs and the long, noncoding RNAs (lncRNAs).

Chapter 11 Completion of the complete nucleotide sequence determination for the human genome in 2022. Focus on the rapidly growing science of bioinformatics: the study of the nature and organization of biological information, including functional genomics and proteomics. New principles emerging about the higher order structural organization of chromosomes, chromosome territories, and chromosome dynamics. Synthetic chromosomes, DNA as a data storage medium.

Chapter 12 Genome engineering with CRISPR-Cas9, CRISPR-Cas9 in gene-editing and base-editing. A new section on human gene therapy, rewriting the human genome.

Chapter 14 A new Critical Developments in Biochemistry box on Nobel laureate Frances Arnold and her pioneering work on the directed evolution of enzymes.

Chapter 17 Metabolites at the center of life, metabolomics as the driver of all the other -omics.

Chapter 18 The newly-discovered protein kinase activity of protein kinase M2 (PK M2), its stimulation by SAICAR (an intermediate in the purine biosynthetic pathway), and its role in tumor proliferation.

Chapter 20 The new molecular structures of the supercomplexes that carry out electron transport and oxidative phosphorylation, including the new structure of Complex I and insights regarding its mechanism of action.

Chapter 22 A new Human Biochemistry box called “Metformin — A Diabetes Drug with Multiple Actions,” and a Critical Developments in Biochemistry feature describing how the consumption of ATP promotes and supports the metabolism of cancer cells.

Chapter 25 Synthesis of cysteine in humans by a reverse transsulfurylation pathway. A new Human Biochemistry box on amino acid metabolism and cancer.

Chapter 26 Figure describing the purinosome metabolon that synthesizes purines on a PRPP platform.

Chapter 27 New molecular graphic of mTORC1, the master integrator of information about nutrient status and a global regulator of biosynthesis. A new section on AMPK inhibition of mTORC1 through reversible phosphorylation. A new section on SIRT1, mTORC1, AMPK, caloric restriction, and metabolic syndrome.

Chapter 28 New discussion and figure illustrating that DNA polymerases are immobilized within replication factories. New figure showing the structural organization of eukaryotic DNA replicons.

Chapter 29 Updated discussion of eukaryotic gene regulatory sequences such as promoters, enhancers, insulators, and silencers.

Chapter 30 Pyrrolysine as the twenty-second amino acid. New art illustrating the richly detailed events in eukaryotic translation initiation.

Chapter 31 New structures of the SecY channel and the SecA ATPase, and cryo-EM structures of co-translational and post-translational states of the Sec61 translocon complex. New cryo-EM structures of a cullin-RING-UBE2D ubiquitin ligation assembly.

Chapter 32 New cryo-EM structure of the neurotensin receptor-arrestin2 complex. New section on ion channels that respond to physical stimuli (including temperature, voltage, pH, redox status, and mechanical phenomena) rather than chemical signals.

Features

- **Clarity of Instruction** This edition was re-organized for increased clarity and readability. Many of the lengthier figure legends were shortened and more information was included directly within illustrations. These changes will help the more visual reader.
- **Visual Instruction** The richness of the Protein Data Bank (www.pdb.org) and availability of molecular graphics software has been exploited to enliven this text. Over 1100 images of prominent proteins and nucleic acids involved with essential biological functions illustrate and inform the subject matter and were prepared especially for this book.
- **Essential Questions Organization** Each chapter in this book is framed around an Essential Question that invites students to become actively engaged in their learning and encourages curiosity and imagination about the subject matter. For example, the Essential Question of Chapter 3 asks, “What are the laws and principles of thermodynamics that allow us to describe the flows and interchanges of heat, energy, and matter in biochemical systems?” The section heads then pose Key Questions that serve as organizing principles for a lecture such as, “What is the daily human requirement for ATP?” The subheadings are designed to be concept statements that respond to the section headings.
- **Foundational Biochemistry** At the end of each chapter, this feature provides a comprehensive list of the principal facts and concepts that a student should understand after reading each chapter. Presented as short statements or descriptive phrases, the items in the Foundational Biochemistry list serve as guides to students of the knowledge they have acquired from the chapter and as checklists the students can review in assessing their learning.
- **End-of-Chapter Problems** More than 700 end-of-chapter problems are provided. They serve as meaningful exercises that help students develop problem-solving skills useful in achieving their learning goals. Some problems require students to employ calculations to find mathematical answers to relevant structural or functional questions. Other questions address conceptual problems whose answers require application and integration of ideas and concepts introduced in the chapter.
- **Think-Pair-Share** problems encourage students to work collaboratively to further their understanding.
- **Further Readings** sections at the end of each chapter make it easy for students to find up-to-date additional information about each topic.

- **Critical Developments in Biochemistry** essays emphasize recent and historical advances in the field.
- **Human Biochemistry** essays emphasize the central role of basic biochemistry in medicine and the health sciences. These essays often present clinically important issues such as diet, diabetes, and cardiovascular health.
- **A Deeper Look** essays expand on the text, highlighting selected topics or experimental observations.
- **Laboratory Techniques** The experimental nature of biochemistry is highlighted, and a list of laboratory techniques found in this book can be seen on page xxxi.

Instructor and Student Resources

Instructor and student resources are available online.

[Instructor resources include:](#)

- Solution and Answer Guide
- Test Bank
- Transition Guide from the Sixth Edition to the Seventh Edition
- Lecture Note PowerPoint slides
- Image Library slides
- Guide to Teaching Online
- Educator's Guide

Acknowledgments

We are indebted to the many experts in biochemistry and molecular biology who carefully reviewed this book at several stages for their outstanding and invaluable advice on how to construct an effective textbook.

[Reviewers for the 7th edition](#)

Bobby Burkes, Grambling State University

Natasha DeVore, Missouri State University

Todd Eckroat, Penn State Behrend

Michael Guy, Northern Kentucky University

Steven Herron, Utah Valley University

Amber Howerton, Nevada State College

Kyoung Nan Kim, University of Colorado, Denver

Steven LaiHing, Oakwood University

Timothy Reichart, Hampden-Sydney College

Stephen Spiro, University of Texas at Dallas

We also wish to gratefully acknowledge many other people who assisted and encouraged us in this endeavor. Roxanne Wang, our Product Manager for Upper-Level Chemistry, has brought enthusiasm and an unwavering emphasis on student learning as the fundamental purpose of our collective enterprise. Meaghan Ford, the Senior Content Manager for this edition, has kept us focused on the matters at hand, the urgencies

of the schedule, and limits of scale in a textbook's dimensions. She is truly a colleague in these endeavors, as is Mona ZefTel, our Learning Designer, whose focus on student learning and student perceptions provided crucial guiderails for us in keeping the education of students uppermost as we created this new edition. We also applaud the unsung but absolutely indispensable contributions by Maria Lokshin, Ph.D., our Development Editor. Maria's editorial grace was precise and immensely helpful. Her writing skills and scientific acumen made this textbook eminently more readable. The contribution of new supplementary end-of-chapter problems by Koen Vercruysse of East Tennessee State University is gratefully acknowledged and appreciated. This book's design and layout is the creative result of work by Chris Doughman. If this book has visual appeal, it is due to Katy Gabel and John Rich, Project Managers at Lumina Datamatics and their colleagues. The beautiful illustrations that not only decorate this text but also explain its contents are a testament to a number of important collaborators. Many colleagues provided original art and graphic images for this book, particularly Professor Jane Richardson of Duke University. We acknowledge with pleasure the scientific and artistic contributions of Michal Sabat of the University of Virginia. Michal was the creator of most of the PyMOL-based molecular graphics in this book. Much of the visual appeal that you will find in these pages gives testimony to his fine craftsmanship and his unflagging dedication to our purpose. Tina Chai, B.S. (Chemistry) graduate of the University of Virginia, his successor and our Molecular Graphics Design specialist, carried his work further. Elizabeth Magnotti, B.S. (Chemistry) graduate of the University of Virginia, and Ph.D., Emory University, pioneered the development of the PSAFE project, a multi-faceted task requiring scientific knowledge and a sense of its importance. Yitna Firdiyew was instrumental in the creation of the PSAFE archive site. Celeste Costa, a current University of Virginia student, prepared content and tutorial videos for the current PSAFE course. We want to acknowledge P. Kelley, of Philander Smith College who audited the content for accuracy, Michael Cascio, of Duquesne University who is writing hints and targeted feedback for new questions for the online course, and Rochelle Williams, of the ARC Network, who advised on inclusivity and diversity for this edition. We owe a special thank you to Rosemary Jurbala Grisham, much loved spouse of Charles and wonderfully tolerant friend of Reg. Also to be acknowledged with love and pride are Georgia Cobb Garrett, spouse of Reg, and our children, Jeffrey, Randal, and Robert Garrett, David and Andrew Grisham, and Emily Grisham Cooke.

We hope this seventh edition of our textbook has captured the growing sense of wonder and imagination that researchers, teachers, and students share as they explore the ever-changing world of biochemistry.

"Imagination is more important than knowledge. For while knowledge defines all we currently know and understand, imagination points to all we might yet discover and create."

The Facts of Life: Chemistry Is the Logic of Biological Phenomena

Marmaduke St. John/Alamy

1

Part I Molecular Components of Cells

“...everything that living things do can be understood in terms of the jiggings and wiggings of atoms.”

Richard P. Feynman. *Lectures on Physics*, Addison-Wesley, 1963

◀ A sperm fertilizing an egg.

Essential Question

Molecules are lifeless. Yet the properties of living things derive from the properties of molecules. **Despite the spectacular diversity of life, the elaborate structure of biological molecules, and the complexity of vital mechanisms, are life functions ultimately interpretable in chemical terms?**

Molecules are lifeless. Yet, in appropriate complexity and number, molecules compose living things. These living systems are distinct from the inanimate world because they have certain extraordinary properties. They can grow, move, perform the incredible chemistry of metabolism, respond to stimuli from the environment, and, most significantly, replicate themselves with exceptional fidelity. The chemistry of the living cell resembles the chemistry of organic reactions. Indeed, cellular constituents, or **biomolecules**, must conform to the chemical and physical principles that govern all matter. Despite the spectacular diversity of life, the intricacy of biological structures, and the complexity of vital mechanisms, life functions are interpretable in chemical terms. *Chemistry is the logic of biological phenomena. Living organisms are self-sustaining systems of chemical reactions.*

1.1 | What Are the Distinctive Properties of Living Systems?

The most obvious quality of **living organisms** is that they are *complicated and highly organized* (Figure 1.1). For example, organisms large enough to be seen with the naked eye are composed of many **cells**, typically of many types. In turn, these cells possess subcellular structures, called **organelles**, which are complex assemblies of very large polymeric molecules, called **macromolecules**. These macromolecules show an exquisite

Key Questions

degree of organization in their intricate three-dimensional architecture, even though they are composed of simple sets of chemical building blocks, such as sugars and amino acids. Indeed, the complex three-dimensional structure of a macromolecule, known as its **conformation**, is a consequence of interactions between the monomeric units, according to their individual chemical properties.

Biological structures serve functional purposes. That is, biological structures play a role in the organism's existence. From parts of organisms, such as limbs and organs, down to the chemical agents of metabolism, such as enzymes and metabolic intermediates, a biological purpose can be given for each component. In biology, it is always meaningful to seek the purpose of observed structures, organizations, or patterns; that is, to ask what functional role they serve within the organism.

Living systems are actively engaged in energy transformations. Maintenance of the highly organized structure and activity of living systems depends on their ability to extract energy from the environment. The ultimate source of energy is the sun. Solar energy flows from photosynthetic organisms (organisms able to capture light energy by the process of photosynthesis) through food chains to herbivores and ultimately to carnivorous predators at the apex of the food pyramid. The biosphere is thus a system through which energy flows. Organisms capture some of this energy, be it from photosynthesis or the metabolism of food, by forming special energized biomolecules. **ATP** and **NADPH** are the two most prominent examples (Figure 1.2). (Commonly used abbreviations such as ATP and NADPH are defined on the inside back cover of this book.) ATP and NADPH are energized biomolecules because they represent chemically useful forms of stored energy. When these molecules react with other molecules in the cell, the energy released can be used to drive energetically unfavorable processes. That is, ATP, NADPH, and related compounds are the power sources that drive the energy-requiring activities of the cell, including biosynthesis, movement, osmotic work against concentration gradients, and, in special instances, light emission (bioluminescence). *The living state is characterized by the flow of energy through the organism.* Only upon death does an organism reach equilibrium with its inanimate environment. At the expense of energy flow, the organism can maintain its intricate order and activity far removed from equilibrium with its surroundings, yet exist in a state of apparent constancy over time. This state of apparent constancy, or so-called **steady state**, is actually a very dynamic condition: Energy and material are consumed by the organism to maintain its stability and order. In contrast, inanimate matter, as exemplified by the universe in totality, is moving to a condition of increasing disorder or, in thermodynamic terms, maximum **entropy**.

Entropy A thermodynamic term used to designate that amount of energy in a system that is unavailable to do work.

Figure 1.2 ATP and NADPH, two biochemically important energy-rich compounds.

Living systems have a remarkable capacity for self-replication. Generation after generation, organisms reproduce virtually identical copies of themselves. This self-replication can proceed by a variety of mechanisms, ranging from simple division in bacteria to sexual reproduction in plants and animals; but in every case, it is characterized by an astounding degree of fidelity (Figure 1.3). Indeed, if the accuracy of self-replication

Figure 1.3 Organisms resemble their parents. Orangutan with infant.

Figure 1.4 The DNA double helix. Two complementary polynucleotide chains run in opposite directions and pair through hydrogen bonding between their nitrogenous bases, A with T and C with G. Note that everywhere there is an A in one strand, the other has a T; everywhere there is a C in one strand, there is a G in the other. These complementary nucleotide sequences give rise to structural complementarity.

In biochemistry and molecular biology, **structurally complementary** means that two structures align and fit together like pieces of a puzzle.

were significantly greater, the evolution of organisms would be hampered. This is so because evolution depends upon natural selection operating on individual organisms that vary slightly in their fitness for the environment. The fidelity of self-replication resides ultimately in the chemical nature of the genetic material. This substance is **deoxyribonucleic acid**, abbreviated as **DNA**. It consists of a pair of polymeric chains built using four different monomers known as deoxynucleotides. These four deoxynucleotide building blocks are symbolized by the letters A, C, G, and T. Information is encoded in each polynucleotide strand in the form of the precise sequence of A, C, G, and T deoxynucleotides along its length, much as this sentence contains information as encoded in the letters of the words that compose it. The two deoxynucleotide chains are **structurally complementary** to one another (Figure 1.4) in that everywhere there is an A in one strand, the other has a T, and everywhere there is a C in one strand, there is a G in the other. DNA can generate two identical copies of itself in a rigorously executed polymerization process whereby each chain is copied precisely, using the information provided by its complementary strand. This process ensures a faithful reproduction of the information written by the original polynucleotide strands. In contrast, the molecules of the inanimate world lack this capacity to replicate. A crude mechanism of replication must have existed at life's origin.

1.2 | What Kinds of Molecules Are Biomolecules?

The elemental composition of living matter differs markedly from the relative abundance of elements in the earth's crust. Hydrogen (H), oxygen (O), carbon (C), and nitrogen (N) constitute more than 99% of the atoms in the human body, with most of the H and O occurring as water, H_2O . Oxygen, silicon (Si), aluminum (Al), and iron (Fe) are the most abundant atoms in the earth's crust, with hydrogen, carbon, and nitrogen being relatively rare (less than 0.2% each). Nitrogen as dinitrogen (N_2) is the predominant gas in the atmosphere, and carbon dioxide (CO_2) is present at a level of 0.04%, a small but critical amount. What property unites hydrogen, oxygen, carbon, and nitrogen and renders these atoms so suitable to the chemistry of life? It is their ability to form covalent bonds by electron-pair sharing. Furthermore, hydrogen, carbon, nitrogen, and oxygen are among the lightest elements of

the periodic table capable of forming such bonds (Figure 1.5). Because the strength of covalent bonds is inversely proportional to the atomic weights of the atoms involved, hydrogen, carbon, nitrogen, and oxygen form the strongest covalent bonds. Two other covalent bond-forming elements, phosphorus (as phosphate $[-\text{OPO}_3^{2-}]$ derivatives) and sulfur, also play important roles in biomolecules.

1.2a Biomolecules Are Carbon Compounds

All biomolecules contain carbon. The prevalence of carbon is due to its unparalleled versatility in forming stable covalent bonds through electron-pair sharing. Carbon can form up to four such bonds by sharing each of the four electrons in its outer shell with electrons contributed by other atoms. Atoms commonly found in covalent linkage to carbon are carbon itself, hydrogen, oxygen, and nitrogen. Hydrogen can form one such bond by contributing its single electron to the formation of an electron pair. Oxygen, with two unpaired electrons in its outer shell, can participate in two covalent bonds, and nitrogen, which has three unshared electrons, can form three such covalent bonds. Furthermore, carbon, nitrogen, and oxygen can share two electron pairs to form double bonds with one another within biomolecules, a property that enhances their chemical versatility. Carbon and nitrogen can even share three electron pairs to form triple bonds.

Two properties of carbon covalent bonds merit particular attention. One is the ability of carbon to form covalent bonds with itself. The other is the tetrahedral nature of the four covalent bonds when carbon atoms form only single bonds. Together these properties hold the potential for an incredible variety of linear, branched, and cyclic carbon compounds. This diversity is multiplied further by the possibilities for including nitrogen, oxygen, and hydrogen atoms in these compounds (Figure 1.6). We can therefore envision the ability of carbon to generate complex structures in three dimensions. These structures, by virtue of appropriately included nitrogen, oxygen, and hydrogen atoms, can display unique chemistries suitable to the living state. Thus, we may ask, is there any pattern or underlying organization that brings order to this astounding potentiality?

1.3 What Is the Structural Organization of Complex Biomolecules?

Examination of the chemical composition of cells reveals a dazzling variety of organic compounds covering chemical dimensions such as length and mass (Table 1.1). When biomolecules are classified based on size and chemical properties, an organizational pattern emerges. The biomolecules are built according to a structural hierarchy: Simple molecules are the units for building complex structures.

The molecular constituents of living matter do not reflect randomly the infinite possibilities for combining carbon, hydrogen, oxygen, and nitrogen atoms. Instead, only a limited set of the many possibilities is found, and these collections share certain properties essential to the living state. The most prominent aspect of biomolecular organization is that simple molecules are the building blocks for polymers that contain thousands or even millions of atoms, structures so large that we refer to them as **macromolecules**. What properties do these biomolecules possess that make them so appropriate for the condition of life?

Macro - prefix from the Greek “makros” meaning large or long.

1.3a Metabolites Are Used to Form the Building Blocks of Macromolecules

The major precursors for the formation of biomolecules are water, carbon dioxide, and three inorganic nitrogen compounds—ammonium (NH_4^+), nitrate (NO_3^-), and dinitrogen (N_2). Metabolic processes transform these inorganic precursors through ever

Table 1.1 Biomolecular Dimensions

The dimensions of mass* and length for biomolecules are given typically in daltons and nanometers,[†] respectively. One dalton (Da) is approximately equal to the mass of one hydrogen atom, 1.66×10^{-24} g. One nanometer (nm) is 10^{-9} m, or 10 Å (angstroms).

Biomolecule	Length (long dimension, nm)	Mass	
		Daltons	Picograms
Water	0.3	18	
Alanine	0.5	89	
Glucose	0.7	180	
Phospholipid	3.5	750	
Ribonuclease (a small protein)	4	12,600	
Immunoglobulin G (IgG)	14	150,000	
Myosin (a large muscle protein)	160	470,000	
Ribosome (bacterial)	18	2,520,000	
Bacteriophage ϕ X174 (a very small bacterial virus)	25	4,700,000	
Pyruvate dehydrogenase complex (a multienzyme complex)	60	7,000,000	
Tobacco mosaic virus (a plant virus)	300	40,000,000	6.68×10^{-5}
Mitochondrion (liver)	1500		1.5
<i>Escherichia coli</i> cell	2000		2
Chloroplast (spinach leaf)	8000		60
Liver cell	20,000		8000

*Molecular mass is expressed in units of daltons (Da) or kilodaltons (kDa) in this book; alternatively, the dimensionless term *molecular weight*, symbolized by M_r , and defined as the ratio of the mass of a molecule to 1 dalton of mass, is used.

[†]Prefixes used for powers of 10 are as follows:

10^6	mega	M	10^{-3}	milli	m
10^3	kilo	k	10^{-6}	micro	μ
10^{-1}	deci	d	10^{-9}	nano	n
10^{-2}	centi	c	10^{-12}	pico	p
			10^{-15}	femto	f

more complex levels of biomolecular order (Figure 1.7). In the first step, precursors are converted to **metabolites**, simple organic compounds that are intermediates in cellular energy transformation and the biosynthesis of various sets of **building blocks**: amino acids, sugars, nucleotides, fatty acids, and glycerol. Through the covalent linkage of these building blocks, **macromolecules** are constructed: proteins, polysaccharides, polynucleotides (DNA and RNA), and lipids. (Strictly speaking, lipids contain relatively few building blocks and are therefore not really polymeric like other macromolecules; however, lipids are important contributors to higher levels of complexity.) Interactions among macromolecules lead to the next level of structural organization, **supramolecular complexes**. Here, various members of one or more of the classes of macromolecules come together to form specific assemblies that serve important sub-cellular functions. Examples of these supramolecular assemblies are multifunctional enzyme complexes, ribosomes, chromosomes, and cytoskeletal elements. For example, a eukaryotic ribosome contains four different RNA molecules and at least 70 unique proteins. Ribosomes are the supramolecular complexes where proteins are synthesized. These supramolecular assemblies are an interesting contrast to their components because their structural integrity is maintained by noncovalent forces, not covalent bonds. These noncovalent forces include hydrogen bonds, ionic attractions, van der Waals forces, and hydrophobic interactions between macromolecules. Such forces maintain these supramolecular assemblies in a highly ordered functional state. Although noncovalent forces are weak (less than 40 kJ/mol), they are numerous in these assemblies and thus can collectively maintain the essential architecture of the supramolecular complex under conditions of temperature, pH, and ionic strength that are consistent with cell life.

Figure 1.7 Molecular organization in the cell is a hierarchy.

1.3b Organelles Represent a Higher Order in Biomolecular Organization

The next higher rung in the hierarchical ladder is occupied by the organelles. Organelles are found only in **eukaryotic cells**, that is, the cells of higher organisms (eukaryotic cells are described in Section 1.5). Organelles are subcellular structures dedicated to a specific purpose. Several kinds, such as mitochondria and chloroplasts, evolved from bacteria that entered the cytoplasm of early eukaryotic cells.

Careers in Chemistry

Michelle Nguyen

Michelle Nguyen is a Vietnamese American immigrant who earned her BS at Ohio State University and decided to stay local to work at Nationwide Children's Hospital in their Compliance and Integrity Office. She considers her work as a Conflict of Interests Administrator to be a mixture of science and law since her responsibilities include mitigating biases within clinical and research programs to protect the integrity of the research. Maintaining scientific impartiality is a crucial step to ensuring overall patient safety.

Nguyen credits her biochemistry education as a fundamental component of her understanding of the research being done and a necessary element to interacting with the doctors and researchers about their work.

Nguyen found her career path after initially pursuing another career in pharmaceuticals but realized that she was truly passionate about life sciences and a major in Biology. Her advice to students still finding their way is to not fear the road less traveled because you might find it more meaningful for you in the end.

Other organelles include the nucleus, endoplasmic reticulum, Golgi apparatus, and vacuoles as well as other relatively small cellular inclusions, such as peroxisomes, lysosomes, and chromoplasts. The **nucleus** is the repository of genetic information contained within the linear sequences of nucleotides in the DNA of chromosomes. **Mitochondria** capture the energy released during aerobic metabolism and use it to produce ATP. **Chloroplasts** endow cells with the ability to carry out photosynthesis, capturing light energy and transforming it into metabolically useful chemical forms.

1.3c Membranes Are Supramolecular Assemblies That Define the Boundaries of Cells

Membranes define the boundaries of cells and organelles. As such, they are not easily classified as supramolecular assemblies or organelles, although they share the properties of both. Membranes resemble supramolecular complexes in their construction because they are complexes of proteins and lipids maintained by noncovalent forces. **Hydrophobic interactions** are particularly important in maintaining membrane structure. Hydrophobic interactions arise because water molecules prefer to interact with each other rather than nonpolar substances. The presence of nonpolar molecules lessens the range of opportunities for water–water interaction by forcing water molecules into ordered arrays around the nonpolar groups. Such ordering can be minimized if the individual nonpolar molecules redistribute from a dispersed state in the water into an aggregated organic phase surrounded by water. The spontaneous assembly of membranes in the aqueous environment, where life arose and exists, is the natural result of the hydrophobic (“water-fearing”) character of lipids and proteins. Hydrophobic interactions are the creative means of membrane formation and the driving force that presumably established the boundary of the first cell. The membranes of organelles, such as nuclei, mitochondria, and chloroplasts, differ from one another, with each having a characteristic protein and lipid composition tailored to the organelle's function. The formation of these discrete compartments in the cell allows these cells to carry out unique functions.

1.3d The Unit of Life Is the Cell

The cell is characterized as the unit of life, the smallest entity capable of displaying the attributes associated uniquely with the living state: growth, metabolism, stimulus response, and replication. In previous discussions, we explicitly narrowed the infinity of chemical complexity potentially available to organic life and we previewed an organizational arrangement, moving from simple to complex, that provides insights into the functional and structural plan of the cell. Nevertheless, these features do not explain the living characteristics of cells. Can we find other themes represented within biomolecules that are explicitly chemical yet anticipate or illuminate the living condition?

1.4 How Do the Properties of Biomolecules Reflect Their Fitness to the Living Condition?

If we consider what attributes of biomolecules render them so fit as components of growing, replicating systems, several biologically relevant themes of structure and organization emerge. Furthermore, as we study biochemistry, we will see that these themes serve as principles of biochemistry. Prominent among them is the *necessity for information and energy in the maintenance of the living state*. Some biomolecules must have the capacity to contain the information, or “recipe,” of life. Other biomolecules must be able to translate this information so that the organized molecules essential to life are synthesized. Interactions between these structures *are* the processes of life. An orderly mechanism for capturing energy from the environment must also exist to obtain the energy needed to drive these processes. What properties of biomolecules endow them with the potential for such remarkable qualities?

1.4a Biological Macromolecules and Their Building Blocks Have a “Sense” or Directionality

The macromolecules of cells are polymers built of monomeric units—amino acids in proteins, nucleotides in nucleic acids, and carbohydrates in polysaccharides—that have **structural polarity**. That is, these building blocks are not symmetrical, and so they can be thought of as having a “head” and a “tail.” Polymerization of these units to form macromolecules occurs by head-to-tail linear connections. Because of this, the polymer also has a head and a tail, and hence, the macromolecule has a “sense” or direction to its structure (Figure 1.8).

Figure 1.8 (a) Amino acids build proteins. (b) Sugars build polysaccharides. (c) Nucleotides build nucleic acids. All these polymerization processes involve bond formations that are accompanied by the elimination of water (dehydration synthesis reactions).

1.4b Biological Macromolecules Are Informational

Because biological macromolecules have a sense to their structure, the sequential order of their component building blocks, when read along the length of the molecule, has the capacity to specify information in the same manner that the letters of the alphabet can form words when arranged in a linear sequence (Figure 1.9). Not all biological macromolecules are rich in information. Polysaccharides are often composed of the same sugar unit repeated over and over, as in cellulose or starch, which are homopolymers of many glucose units. On the other hand, proteins and polynucleotides are typically composed of building blocks arranged without an obvious pattern; that is, their sequences are unique, akin to the letters and punctuation that form this descriptive sentence. In these unique sequences lies meaning.

In 1957, Francis Crick laid the foundation for molecular biology when he postulated a pathway for the flow of information in biological systems. This information is encoded in the sequence of building blocks arrayed along informational macromolecules. Crick reasoned that information flows from DNA, the hereditary material and the repository of that information, through an RNA intermediate that serves as a message to specify the sequence of amino acids in a protein, as summarized in the scheme below:

RNA resembles DNA. In it, U replaces T as one of the four nucleotide building blocks.

As we will see, a gene is a sequence of nucleotides in DNA that encodes the information to build a protein with a particular amino acid sequence. Significantly, proteins are the agents of biological function—they underlie virtually all of the activities that a cell or organism displays:

In macromolecular terms,

In informational terms,

A nucleotide sequence in DNA is transcribed and written as an RNA sequence, and that RNA sequence is translated as a sequence of amino acids in a protein. Crick's pathway of information transfer has become **the central dogma of molecular biology**.

A strand of DNA

A polypeptide segment

A polysaccharide chain

Figure 1.9 The sequence of monomeric units in a biological polymer can contain information if the diversity and order of the units are not overly simple or repetitive. Nucleic acids and proteins are information-rich molecules; polysaccharides are not.

Figure 1.10 Antigen-binding domain of immunoglobulin G (IgG). **(a)** Space-filling model showing each atom as a sphere. **(b)** Ribbon diagram representation. Each flat arrow represents a region of regular 3-dimensional structure containing 5 to 15 amino acids. PDB ID = 1FDL.

1.4c Biomolecules Have Characteristic Three-Dimensional Architecture

The structure of any molecule is a unique and specific aspect of its identity. Molecular structure reaches its pinnacle in the intricate complexity of biological macromolecules, particularly proteins. Although proteins are linear sequences of covalently linked amino acids, the course of the protein chain can turn, fold, and coil in the three dimensions of space to establish a specific, highly ordered architecture that is an identifying characteristic of the given protein molecule (Figure 1.10).

1.4d Weak Forces Maintain Biological Structure and Determine Biomolecular Interactions

Covalent bonds hold atoms together so that molecules are formed. In contrast, **weak chemical forces** or **noncovalent bonds** (hydrogen bonds, van der Waals forces, ionic interactions, and hydrophobic interactions) are intramolecular or intermolecular attractions between atoms. None of these forces, which typically range from 4 to 30 kJ/mol, are strong enough to bind free atoms together (Table 1.2). The average kinetic energy of molecules at 25°C is 2.5 kJ/mol, so the energy of weak forces is only several times greater than the dissociating tendency due to thermal motion of molecules. Thus, these weak forces establish interactions that are constantly forming and breaking at physiological temperatures. However, through collective action, large numbers of weak forces can create, organize, and stabilize complex structures. These weak forces merit further discussion because their properties profoundly influence the nature of the biological structures they build.

1.4e Van der Waals Forces Are Short-Range Interactions between Atoms in Nearby Molecules

Van der Waals forces result from the induced electrical interactions between closely approaching atoms or molecules as their negatively charged electron clouds fluctuate instantaneously in time. These fluctuations allow attraction to occur between the positively charged nuclei and the electrons of nearby atoms. Van der Waals attractions operate over a very limited interatomic distance (0.3 to 0.6 nm) and are an effective bonding interaction at physiological temperatures only when a number of atoms in a molecule can interact with several atoms in a neighboring molecule. For this to occur, the atoms on interacting molecules must pack together neatly. That is, their molecular surfaces must possess a degree of structural complementarity (Figure 1.11).

At best, van der Waals interactions are weak and individually contribute 0.4 to 4.0 kJ/mol of stabilization energy. However, the sum of many such interactions within a

Table 1.2 Weak Chemical Forces and Their Relative Strengths and Distances

Force	Strength (kJ/mol)	Distance (nm)	Description
Van der Waals interactions	0.4–4.0	0.3–0.6	Strength depends on the relative size of the atoms or molecules and the distance between them. The size factor determines the area of contact between two molecules: The greater the area, the stronger the interaction.
Hydrogen bonds	12–30	0.3	Relative strength is proportional to the polarity of the H bond donor and H bond acceptor. More polar atoms form stronger H bonds.
Ionic interactions	20	0.25	Strength also depends on the relative polarity of the interacting charged species. Some ionic interactions are also H bonds: $\text{—NH}_3^+ \cdots \text{—OOC—}$.
Hydrophobic interactions	<40	—	Force is a complex phenomenon determined by the degree to which the structure of water is disordered as discrete hydrophobic molecules or molecular regions coalesce.

Figure 1.11 Van der Waals packing is enhanced in molecules that are structurally complementary. Gln¹²¹, a surface protuberance on lysozyme, is recognized by the antigen-binding site of an antibody against lysozyme. Gln¹²¹ (pink) fits nicely in a pocket formed by Tyr³² (orange), Phe⁹¹ (light green), Trp⁹² (dark green), and Tyr¹⁰¹ (blue) components of the antibody. (See also Figure 1.15.) (a) Ball-and-stick model. (b) Space-filling representation. (From Amit, A. G., et al., 1986. Three-dimensional structure of an antigen-antibody complex at 2.8 Å resolution. *Science* **233**:747–753, figure 5.)

macromolecule or between macromolecules can be substantial. Calculations indicate that the attractive van der Waals energy between the enzyme lysozyme and a sugar substrate that it binds is about 60 kJ/mol.

When two atoms approach each other so closely that their electron clouds begin to overlap, strong *repulsive* van der Waals forces occur, as shown in Figure 1.12. Between the repulsive and attractive domains lies a low point in the potential curve. This low point defines the distance known as the **van der Waals contact distance**, which is the interatomic distance that results if only van der Waals forces hold two atoms together. The limit of approach of two atoms is determined by the sum of their van der Waals radii (Table 1.3).

Table 1.3 Radii of Common Biomolecular Atoms

Atom	Van der Waals Radius (nm)	Covalent Radius (nm)	Atom Represented to Scale
H	0.1	0.037	○
C	0.17	0.077	●
N	0.15	0.070	●
O	0.14	0.066	●
P	0.19	0.096	●
S	0.185	0.104	●
Half-thickness of an aromatic ring	0.17	—	

Figure 1.12 The van der Waals interaction energy profile as a function of the distance, r , between the centers of two atoms.

H bonds Bonded atoms	Approximate bond length*
O—H---O	0.27 nm
O—H---O ⁻	0.26 nm
O—H---N	0.29 nm
N—H---O	0.30 nm
⁺ N—H---O	0.29 nm
N—H---N	0.31 nm

*Lengths given are distances from the atom covalently linked to the H to the atom H bonded to the hydrogen:

$$\begin{array}{c} \text{O} - \text{H} - - - \text{O} \\ | \quad \quad \quad | \\ \leftarrow 0.27 \text{ nm} \rightarrow \end{array}$$

Functional groups that are important H-bond donors and acceptors:	
Donors	Acceptors

Figure 1.13 Some biologically important H bonds.

1.4f Hydrogen Bonds Form between H Atoms and Electronegative Atoms Like N and O

Hydrogen bonds form between a hydrogen atom covalently bonded to an electronegative atom (such as oxygen or nitrogen) and a second electronegative atom that serves as the hydrogen bond acceptor. Several important biological examples are given in Figure 1.13. Hydrogen bonds, at a strength of 12 to 30 kJ/mol, are stronger than van der Waals forces and have an additional property: H bonds are cylindrically symmetrical and tend to be highly directional, forming straight bonds between donor, hydrogen, and acceptor atoms. Hydrogen bonds are also more specific than van der Waals interactions because they require the presence of complementary hydrogen donor and acceptor groups.

1.4g Ionic Interactions Form between Oppositely Charged Groups or Molecules

Ionic interactions, also called electrostatic interactions, are the result of forces between electrically charged structures, such as negative carboxyl groups and positive amino groups (Figure 1.14). These electrostatic forces average about 20 kJ/mol in aqueous solutions. Typically, the electrical charge is radially distributed, so these interactions may lack the directionality of hydrogen bonds or the precise fit of van der Waals interactions. Nevertheless, because the opposite charges are restricted to sterically defined positions, ionic interactions can impart a high degree of structural specificity.

The strength of electrostatic interactions is highly dependent on the nature of the interacting species and the distance, r , between them. Electrostatic interactions may involve **ions** (species possessing discrete charges), **permanent dipoles** (a permanent separation of positive and negative charge), or **induced dipoles** (a temporary separation of positive and negative charge induced by the environment).

1.4h Hydrophobic Interactions Are the Result of Favorable Interactions between Water Molecules

Hydrophobic interactions result from the strong tendency of water to exclude nonpolar groups or molecules (see Chapter 2). Hydrophobic interactions arise not because of any intrinsic affinity of nonpolar substances for one another (although van der Waals forces do promote the weak bonding of nonpolar substances), but because water molecules prefer the stronger interactions that they share with one another, compared to their interactions with nonpolar molecules. Hydrogen-bonding interactions between polar water molecules can be more varied and numerous if nonpolar molecules merge into a distinct organic phase. This phase separation raises the entropy of water because individual nonpolar molecules are no longer dispersed in the water, and thus, water molecules are no longer arranged in orderly arrays around them. It is these preferential interactions between water molecules that “exclude” hydrophobic substances from aqueous solution and drive the tendency of nonpolar molecules to cluster together. Thus, nonpolar regions of biological macromolecules are often buried in the molecule’s interior to exclude them from the aqueous milieu. The formation of oil droplets as hydrophobic nonpolar lipid molecules that coalesce in the presence of water is an approximation of this phenomenon. These tendencies have important consequences in the creation and maintenance of the macromolecular structures and supramolecular assemblies of living cells.

1.4i The Defining Concept of Biochemistry Is “Molecular Recognition through Structural Complementarity”

The complicated and highly organized patterns of life depend on the ability of biomolecules to recognize and interact with one another in very specific ways. Such interactions are fundamental to metabolism, growth, replication, and other vital

processes. The interaction of one molecule with another, a protein with a metabolite, for example, is most precise if the structure of one is complementary to the structure of the other, as in two connecting pieces of a puzzle or, in the more popular analogy for macromolecules and their **ligands**, a lock and its key (Figure 1.15). Structural complementarity is the means of recognition in biomolecular interactions. Indeed, this *principle of structural complementarity is the very essence of biomolecular recognition*. Structural complementarity is the clue to understanding the functional properties of biological systems. Biological systems, from the macromolecular level to the cellular level, operate via specific molecular recognition mechanisms based on structural complementarity: A protein recognizes its specific metabolite, an antibody recognizes its antigen, a strand of DNA recognizes its complementary strand, sperm recognize an egg. All these interactions involve structural complementarity between molecules.

1.4j Biomolecular Recognition Is Mediated by Weak Chemical Forces

The weak chemical forces described earlier underlie the interactions that are the basis of biomolecular recognition. It is important to realize that because these interactions are sufficiently weak, they are readily reversible. Consequently, biomolecular interactions tend to be transient; rigid, static lattices of biomolecules that might paralyze cellular activities are not formed. Instead, a dynamic interplay occurs between metabolites and macromolecules, hormones and receptors, and all the other participants instrumental to life processes. This interplay is initiated upon specific recognition between complementary molecules and ultimately results in unique physiological activities. Biological function is achieved through mechanisms based on structural complementarity and weak chemical interactions.

This principle of structural complementarity extends to higher interactions essential to the establishment of the living condition. For example, the formation of supramolecular complexes occurs because of recognition and interaction between their various macromolecular components, as governed by the weak forces formed between them. If a sufficient number of weak bonds can be formed, as between macromolecules complementary in structure to one another, larger structures assemble spontaneously. The tendency for nonpolar molecules and parts of molecules to come together through hydrophobic interactions also promotes the formation of supramolecular assemblies. Very complex subcellular structures are actually spontaneously formed in an assembly process that is driven by weak forces accumulating through structural complementarity.

Figure 1.14 Ionic bonds in biological molecules. **(a)** Magnesium ATP. **(b)** Intramolecular ionic bonds between oppositely charged groups on amino acid residues in a protein.

Ligand a molecule (or atom) that binds specifically to another molecule (from Latin *ligare*, to bind).

Figure 1.15 Structural complementarity: **(a)** the pieces of a puzzle, **(b)** the lock and its key, **(c)** a biological macromolecule and its ligand—an antigen–antibody complex. The antigen on the right (*gold*) is a small protein, lysozyme, from hen egg white. The antibody molecule (IgG) (*left*) has a pocket that is structurally complementary to a surface feature (*red*) on the antigen. (See also Figure 1.11.)

1.4k Weak Forces Restrict Organisms to a Narrow Range of Environmental Conditions

Because biomolecular interactions are governed by weak forces, living systems are restricted to a narrow range of physical conditions. Biological macromolecules are functionally active only within a narrow range of environmental conditions, such as temperature, ionic strength, and relative acidity. Extremes of these conditions disrupt the weak forces essential to maintaining the intricate structure of macromolecules. The loss of structural order in these complex macromolecules, so-called **denaturation**, is accompanied by loss of function (Figure 1.16). As a consequence, cells cannot tolerate reactions in which large amounts of energy are released, nor can they generate a large energy burst to drive energy-requiring processes. Instead, such transformations take place via sequential series of chemical reactions whose overall effect achieves dramatic energy changes, even though any given reaction in the series proceeds with only a modest input or release of energy (Figure 1.17). These sequences of reactions

Figure 1.16 Denaturation and renaturation of an intricate protein structure.

The combustion of glucose: $\text{C}_6\text{H}_{12}\text{O}_6 + 6 \text{O}_2 \longrightarrow 6 \text{CO}_2 + 6 \text{H}_2\text{O} + 2870 \text{ kJ energy}$

(a) In an aerobic cell

(b) In a bomb calorimeter

Figure 1.17 Metabolism is the organized release or capture of small amounts of energy when the overall energy change is large. (a) Cells can release energy from glucose in a stepwise fashion, and the small “packets” of energy are used as ATP. (b) Combustion of glucose in a bomb calorimeter results in an uncontrolled, explosive release of energy in its least useful form, heat.

are organized to release useful energy to the cell from the breakdown of food or to take such energy and use it to drive the synthesis of biomolecules essential to the living state. Collectively, these reaction sequences constitute cellular **metabolism**—the ordered reaction pathways by which cellular chemistry proceeds and biological energy transformations are accomplished.

1.4l Enzymes Catalyze Metabolic Reactions

The sensitivity of cellular constituents to environmental extremes places another constraint on the reactions of metabolism. The rate at which cellular reactions proceed is a very important factor in maintaining the living state. However, the common ways that chemists accelerate reactions are not available to cells; the temperature cannot be raised, acid or base cannot be added, the pressure cannot be elevated, and concentrations cannot be dramatically increased. Instead, biomolecular catalysts mediate cellular reactions. These catalysts, called **enzymes**, accelerate the reaction rates by many orders of magnitude and, by selecting the substances undergoing reaction, determine the specific reaction that takes place. Virtually every metabolic reaction is catalyzed by an enzyme (Figure 1.18).

Metabolic Regulation Is Achieved by Controlling the Activity of Enzymes Thousands of reactions mediated by an equal number of enzymes are occurring at any given instant within the cell. Collectively, these reactions constitute cellular metabolism. Metabolism has many branch points, cycles, and interconnections, as subsequent chapters reveal. All these reactions, many of which are at apparent cross-purposes in the cell, must be fine-tuned and integrated so that metabolism and life proceed harmoniously. This metabolic regulation is achieved through controls on enzyme activity so that the rates of cellular reactions are appropriate to cellular requirements.

Despite the organized pattern of metabolism and the thousands of enzymes required, cellular reactions conform to the same thermodynamic principles that govern any chemical reaction. Enzymes have no influence over energy changes (the thermodynamic component) in their reactions. Enzymes only influence reaction rates. Thus, cells rely on enzyme-based metabolic systems that take in food, release waste, and carry out complex degradative and biosynthetic reactions essential to their survival while maintaining a constant internal environment (**homeostasis**) with no outwardly apparent changes. Cells are open thermodynamic systems that exchange matter and energy with their environment and function as highly regulated isothermal chemical engines.

1.4m Biomolecular Phenomena across the Time Scale of Life

Individual organisms have life spans ranging from a day or less to a century or more, but the phenomena that characterize and define living systems have durations ranging over 33 orders of magnitude, from 10^{-15} sec (electron transfer reactions, photo excitation in photosynthesis) to 10^{18} sec (the period of evolution, spanning from the first appearance of organisms on the earth more than 3 billion years ago to today) (Table 1.4). Because proteins are the agents of biological function, phenomena involving weak interactions and proteins dominate the shorter times. As time increases, more stable interactions (covalent bonds) and phenomena involving the agents of genetic information (the nucleic acids) come into play.

Figure 1.18 Carbonic anhydrase, a representative enzyme. This macromolecule is a polymer of 260 amino acids and is composed of more than 2200 atoms. Its structure is represented as a ribbon diagram. Ribbon diagrams are useful summaries of a macromolecule's 3D structural features.

1.5 | What Are the Organization and Structure of Cells?

All living cells fall into one of three broad categories—**Archaea**, **Bacteria**, and **Eukarya**. Archaea and Bacteria are referred to collectively as **prokaryotes**. As a group, prokaryotes are single-celled organisms that lack nuclei and other organelles; the word is derived from *pro* meaning “prior to” and *karyot* meaning “nucleus.” In

Table 1.4 Life Times		
Time (sec)	Process	Example
10^{-15}	Electron transfer	The light reactions in photosynthesis.
10^{-13}	Transition states	Transition states in chemical reactions have lifetimes of 10^{-11} to 10^{-15} sec (the reciprocal of the frequency of bond vibrations).
10^{-11}	H-bond lifetimes	H bonds are exchanged between H_2O molecules due to the rotation of the water molecules themselves.
10^{-12} to 10^3	Motion in proteins	Fast: tyrosine ring flips, methyl group rotations Slow: bending motions between protein domains
10^{-6} to 10^0	Enzyme catalysis	10^{-6} sec: fast enzyme reactions 10^{-3} sec: typical enzyme reactions 10^0 sec: slow enzyme reactions
10^0	Diffusion in membranes	A typical membrane lipid molecule can diffuse from one end of a bacterial cell to the other in 1 sec; a small protein would go half as far.
10^1 to 10^2	Protein synthesis	Some ribosomes synthesize proteins at a rate of 20 amino acids added per second.
10^4 to 10^5	Cell division	Prokaryotic cells can divide as rapidly as every hour or so; eukaryotic cell division varies greatly (from hours to years).
10^7 to 10^8	Embryonic development	Human embryonic development takes 9 months (2.4×10^7 sec).
10^5 to 10^9	Life span	Human life expectancy is about 80 years in developed countries (2.5×10^9 sec).
10^{18}	Evolution	The first organisms appeared 3.8×10^9 years ago and evolution has continued since then.

traditional biological classification schemes, prokaryotes were grouped together as members of the kingdom Monera. The other four living kingdoms were all Eukarya—the single-celled Protists, such as amoebae, and all multicellular life forms, including the Fungi, Plant, and Animal kingdoms. Eukaryotic cells have true nuclei and other organelles such as mitochondria, with the prefix *eu* meaning “true.” Groupings of organisms into kingdoms is useful, but Eukarya are a more complex domain of life than earlier classification schemes suggest.

1.5a The Eukaryotic Cell Likely Emerged from an Archaeal Lineage

In the three-domain tree of life, Archaea, Bacteria, and Eukarya share a common ancestry, arising from primordial cells that exchanged genetic information among themselves. Current evidence suggests that, early on, Archaea and Bacteria were the two principal domains of life, and eukaryotic cells emerged when an archaeal cell hosted one or more bacterial partners. That is, contemporary eukaryotic cells are composite cells that harbor archaeal and bacterial contributions.

Despite great diversity in form and function, cells and organisms share much biochemistry in common. This commonality was substantiated by the results of **whole genome sequencing**, the determination of the complete nucleotide sequence within the DNA of an organism. For example, the genome of the metabolically divergent archaea *Methanococcus jannaschii* shows 44% similarity to known genes in eubacteria and eukaryotes.

1.5b How Many Genes Does a Cell Need?

The *Mycoplasma genitalium* genome consists of 523 genes, encoding 484 proteins, in just 580,074 base pairs (Table 1.5). Note that some flowering plants (*Arabidopsis thaliana*) and animals (pufferfish) have more genes than humans. Thus, the number of genes does not correlate directly with biological complexity. This information sparks an interesting question: How many genes are needed for cellular life?

Table 1.5 How Many Genes Does It Take to Make An Organism?

Organism	Number of Cells in Adult*	Number of Genes
<i>Mycobacterium genitalium</i> Pathogenic bacterium	1	523
<i>Methanococcus jannaschii</i> Archaeal methanogen	1	1800
<i>Escherichia coli</i> K12 Intestinal bacterium	1	4400
<i>Saccharomyces cerevisiae</i> Baker's yeast (eukaryote)	1	6000
<i>Caenorhabditis elegans</i> Nematode worm	959	19,000
<i>Drosophila melanogaster</i> Fruit fly	10 ⁴	13,500
<i>Arabidopsis thaliana</i> Flowering plant	10 ⁷	27,000
<i>Fugu rubripes</i> Pufferfish	10 ¹²	26,700 (est.)
<i>Homo sapiens</i> Human	10 ¹⁴	20,500 (est.)

The first four of the nine organisms in the table are single-celled microbes; the last six are eukaryotes; the last five are multicellular, four of which are animals; the final two are vertebrates. Although pufferfish and humans have roughly the same number of genes, the pufferfish genome, at 0.365 billion nucleotide pairs, is only one-eighth the size of the human genome.

*Numbers for *Arabidopsis thaliana*, the pufferfish, and human are "order-of-magnitude" rough estimates.

Critical Developments in Biochemistry

Synthetic Life

If life is chemistry, can we use chemistry to create life? J. Craig Venter and his colleagues at the J. Craig Venter Institute (JCVI) claim to have created the first synthetic life. They devised a synthetic version of the 1.08×10^6 -base pair genome of *Mycobacterium mycoides* by designing a thousand segments of DNA, each about 1000 base pairs long, which were then chemically synthesized by the Blue Heron Biotechnology Co., a DNA synthesizing service. The JCVI scientists then assembled these pieces to form a complete synthetic genome that was transferred into the cytoplasm of a related bacterial species, *M. capricolum*. The self-replicating cells that grew following this genome transplantation were under the direction of the synthetic genome and produced proteins representative of *M. mycoides*, not *M. capricolum*. Further, the only DNA in these cell

cultures was the synthetic DNA created by Venter and associates, as evidenced by certain "watermarks" they designed into their synthetic genome to establish its uniqueness. These cells represent the first artificial living organisms, artificial in the sense that their entire genome was chemically synthesized and not the result of biological evolution. Their significance lies in the possibilities they open for the creation of life forms for specific purposes, such as oil-eating bacteria for environmental remediation or bacteria that synthesize desired products such as drugs.

Gibson, D. G., 2010. Creation of a bacterial cell controlled by a chemically synthesized genome. *Science* **329**:52–56.

Any **minimum gene set** must encode all the information necessary for cellular metabolism, including the vital functions essential to reproduction. The simplest cell must show at least some degree of metabolism and energy production; genetic replication based on a template molecule that encodes information (DNA or RNA?); and formation and maintenance of a cell boundary (membrane). Top-down studies aim to discover from existing cells what a minimum gene set might be. These studies have focused on simple parasitic bacteria because parasites often obtain many substances from their hosts and do not have to synthesize them from scratch; thus, they require fewer genes. One study concluded that 206 genes are

Gene A unit of hereditary information, physically defined by a specific sequence of nucleotides in DNA; in molecular terms, a gene is a nucleotide sequence that encodes a protein or an RNA product.

sufficient to form a minimum gene set. The set included genes for DNA replication and repair, transcription, translation, protein processing, cell division, membrane structure, nutrient transport, metabolic pathways for ATP synthesis, and enzymes to make a small number of metabolites that might not be available, such as pentoses for nucleotides. Another study based on computer modeling decided that a minimum gene set might have only 105 protein-coding genes. Bottom-up studies aim to create a minimal cell by reconstruction based on known cellular components. The simplest, functional artificial cell capable of replication would contain an informational macromolecule (presumably a nucleic acid) and enough metabolic apparatus to maintain a basic set of cellular components within a membrane-like boundary.

1.5c Archaea and Bacteria Have a Relatively Simple Structural Organization

The bacteria form a widely distributed group. Certain of them are pathogenic to humans. The archaea, about which less is known, were first discovered growing in unusual environments where other cells cannot survive. Archaea include the **thermoacidophiles** (heat- and acid-loving bacteria) of hot springs, the **halophiles** (salt-loving bacteria) of salt lakes and ponds, and the **methanogens** (bacteria that generate methane from CO_2 and H_2). Archaea are also common in typical microbial habitats, such as soils, seas, and the guts of animals. Bacteria and Archaea, collectively known as Prokaryota, are typically very small, on the order of several microns in length, and are usually surrounded by a rigid **cell wall** that protects the cell and gives it its shape. The characteristic structural organization of one of these cells is depicted in Figure 1.19.

Prokaryotic cells have only a single membrane, the **plasma membrane** or **cell membrane**. Because they have no other membranes, prokaryotic cells contain no nucleus or organelles. Nevertheless, they possess a distinct nuclear area called the **nucleoid**

Figure 1.19 This bacterium is *Escherichia coli*, a member of the coliform group of bacteria that colonize the human intestinal tract. **(a)** Micrograph of a cross section of *E. coli* cells, **(b)** a micrograph of a cluster of *E. coli* cells, and **(c)** a schematic drawing of an *E. coli* cell. Diphtheria	<i>Corynebacterium diphtheriae</i>
Tuberculosis	<i>Mycobacterium tuberculosis</i>
Leprosy	<i>Mycobacterium leprae</i>
Gonorrhea	<i>Neisseria gonorrhoeae</i>

where a single circular chromosome is localized. Some have internal membranous structures derived from and continuous with the cell membrane. Reactions of cellular energy production are localized mainly on these membranes. In **cyanobacteria**, flat, sheet-like membranous structures called **lamellae** are formed from cell membrane infoldings. These lamellae are the sites of photosynthesis. Some bacteria have **flagella**, single, long filaments used for motility. Prokaryotes largely reproduce by asexual division, although sexual exchanges can occur. Table 1.6 lists a few of the many diseases caused by bacteria.

1.5d The Structural Organization of Eukaryotic Cells Is More Complex Than That of Prokaryotic Cells

Compared with prokaryotic cells, eukaryotic cells are much greater in size, typically having cell volumes 10^3 to 10^4 times larger. They are also much more complex. These two features require that eukaryotic cells partition their diverse metabolic processes into organized compartments, with each compartment dedicated to a particular function. A system of internal membranes accomplishes this partitioning. A typical animal cell is shown in Figure 1.20 and a typical plant cell in Figure 1.21.

Eukaryotic cells possess a discrete, membrane-bounded **nucleus**, the repository of the cell's genetic material, which is distributed among a few or many **chromosomes**. During cell division, equivalent copies of this genetic material must be passed to both daughter cells through duplication and orderly partitioning of the chromosomes by the process known as **mitosis**. Like prokaryotic cells, eukaryotic cells are surrounded by a plasma membrane. Unlike prokaryotic cells, eukaryotic cells are rich in internal membranes that are differentiated into specialized structures such as the **endoplasmic reticulum (ER)** and the **Golgi apparatus**. Ribosomes associated with the rough ER are the site of membrane protein synthesis. Thirty percent of cellular proteins are inserted into the ER membrane. The Golgi apparatus is involved in the packaging and processing of proteins destined for secretion from the cell. All of these internal membrane systems connect to one another and ultimately to the plasma membrane. Membranes also surround certain organelles (**mitochondria** and **chloroplasts**, for example) and various vesicles, including **vacuoles**, **lysosomes**, and **peroxisomes**. The common purpose of these membranous partitionings is the creation of cellular compartments that have specific, organized metabolic functions, such as the mitochondrion's role as the principal site of cellular energy production. Eukaryotic cells also have a **cytoskeleton** composed of arrays of filaments that give the cell its shape and its capacity to move. Some eukaryotic cells also have long projections on their surface—cilia or flagella—which provide propulsion.

1.6 | What Are Viruses?

Viruses are supramolecular complexes of nucleic acid (either DNA or RNA) encapsulated in a protein coat and, in some instances, surrounded by a membrane envelope (Figure 1.22). Viruses are acellular, but they act as cellular parasites to reproduce. The bits of nucleic acid in viruses are mobile elements of genetic information. The protein coat serves to protect the nucleic acid and allows it to gain entry to the cells that are its specific hosts. No cell type is free from virus attack. Viruses infecting bacteria are called **bacteriophages** (“bacteria eaters”); different viruses infect animal cells and plant cells. Once the nucleic acid of a virus gains access to its host, it typically takes over the metabolic machinery of the host cell, diverting it to the production of virus particles. The host metabolic functions are subjugated to the synthesis of viral nucleic acid and proteins. Mature virus particles arise by encapsulating the newly synthesized viral nucleic acid within a protein coat called the **capsid**. Thus, viruses are supramolecular assemblies that act as parasites of cells (Figure 1.23).

A PLANT CELL

Figure 1.21 This figure diagrams a cell in the leaf of a higher plant. The cell wall, membrane, nucleus, chloroplasts, mitochondria, vacuole, endoplasmic reticulum (ER), and other characteristic features are shown.

Figure 1.22 Viruses are genetic elements enclosed in a protein coat. Viruses are not free-living organisms and can reproduce only within cells. Viruses have an almost absolute specificity for their host cells, infecting and multiplying only within those cells. Viruses are known that infect virtually every kind of cell. Shown here are examples of (a) SARS2-CoV-2 coronavirus, the virus that causes COVID-19, (b) bacteriophage T4 on its host, *E. coli*; and (c) a plant virus, the tobacco mosaic virus.

Figure 1.23 The virus life cycle. Viruses are mobile bits of genetic information encapsulated in a protein coat. The genetic material can be either DNA or RNA. Once this genetic material enters its host cell, it takes over the host machinery for macromolecular synthesis and subverts it to synthesize virus-specific nucleic acids and proteins. These viral components are then assembled into virus particles that are released from the cell. Often, this parasitic cycle of virus infection leads to cell death and disease.

Often, viruses cause disintegration of the cells that they have infected, a process referred to as **cell lysis**. It is their cytolytic properties that are the basis of viral disease. In certain circumstances, the viral genetic elements may integrate into the host chromosome and become quiescent. Such a state is termed **lysogeny**. Typically, damage to the host cell activates the replicative capacities of the quiescent viral nucleic acid, leading to viral propagation and release. Some viruses are implicated in transforming cells into a cancerous state, that is, in converting their hosts to an unregulated state of cell division and proliferation. Because all viruses are heavily dependent on their host for the production of viral progeny, viruses must have evolved after cells were established. Presumably, the first viruses were fragments of nucleic acid that developed the ability to replicate independently of the chromosome and then acquired the necessary genes enabling protection, autonomy, and transfer between cells. Surprisingly, virus-related DNA makes up almost half of the human genome.

Table 1.7 Some Human Diseases Caused by Viruses	
Disease	Causative Agent
Caused by DNA Viruses	
Measles	Measles morbillivirus
Mumps	Mumps paramyxovirus
Hepatitis B	Hepadnavirus
Influenza (flu)	Orthomyxovirus
Chickenpox	Varicella-zoster virus
Smallpox	Orthopoxvirus variola virus
Dengue	Flavivirus dengue virus
Caused by RNA Viruses	
Hepatitis A	Hepatovirus A
Hepatitis C	Hepacivirus C
Common cold	Rhinoviruses
Polio	Enterovirus C poliovirus
Shingles	Varicella-zoster virus
Rabies	Rabies lyssavirus
AIDS	Human immunodeficiency virus (HIV)
COVID-19	SARS-CoV-2 coronavirus

Foundational Biochemistry Things You Should Know after Reading Chapter 1.

- Chemistry is the logic of biological phenomena.
- Biological molecules serve functional purposes.
- The living state is characterized by the flow of energy through the organism.
- Biomolecules are compounds of carbon.
- Cellular macromolecules and structures are formed from simple molecules.
- Metabolites are used to form the building blocks of macromolecules.
- Membranes are supramolecular assemblies that define the boundaries of cells.
- Biological macromolecules and their building blocks have a “sense,” or directionality.
- Biological macromolecules are informational.
- Macromolecules have a defining three-dimensional architecture.
- Weak forces important in biochemistry include van der Waals interactions, hydrogen bonds, electrostatic (ionic) interactions, and hydrophobic interactions.
- Weak forces maintain biological structure and determine biomolecular interactions.
- Molecular recognition through structural complementarity is the defining concept in biochemistry.
- Biomolecular recognition is mediated by weak chemical forces.
- The importance of weak forces restricts organisms to a narrow range of environmental conditions.
- Enzymes catalyze metabolic reactions.
- Metabolic regulation is achieved by controlling the activity of enzymes.
- The time scale of life ranges from 10^{-15} sec (the speed of electron transfer processes) to 10^{18} sec, the time span that life has been evolving on earth.
- Prokaryotic cells have a simple structural and functional organization.
- Plants and animals are composed of eukaryotic cells, which have organelles and a more complex structural and functional organization.
- Viruses are lifeless complexes of nucleic acid and protein that act as cellular parasites to reproduce.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. The Principle of Molecular Recognition through Structural Complementarity** Biomolecules interact with one another through molecular surfaces that are structurally complementary.
 - a. What properties must proteins possess to interact with molecules as different as simple ions, hydrophobic lipids, polar but uncharged carbohydrates, and nucleic acids?
 - b. Consult Table 1.1 to compare the size of alanine (an amino acid) and immunoglobulin (a protein). Assume this protein can interact with alanine. What conclusions can you draw about the relative surface area of the protein and the parts of it that interact with alanine. (Section 1.4)
- 2. The Properties of Informational Macromolecules** What organizational features allow biological polymers to be informational macromolecules? Is it possible for polysaccharides to be informational macromolecules? (Section 1.4)
- 3. Proteins and Nucleic Acids Are Informational Macromolecules** What are the two essential criteria for a linear polymer to be an informational macromolecule?
- 4. Structure and Function** DNA molecules adopt the famous double-helix shape (see Figure 1.4). Proteins adopt a variety of shapes (see Figures 1.10 and 1.16). Based on your understanding of the central dogma of molecular biology (see section 1.4b), provide a possible explanation for why DNA molecules adopt one shape whereas proteins have multiple different shapes?
- 5. The Importance of Weak Forces in Biomolecular Recognition** Why is it important that weak forces, not strong forces, mediate biomolecular recognition? (Section 1.4)
- 6. Biological Molecules Often Interact via Weak Forces.**
 - a. How can you change the kinetic energy in a system of interacting molecules?
 - b. Predict the effect on such interactions of
 - 1) an increase in kinetic energy.
 - 2) a decrease in kinetic energy.

- 7. Building Macromolecules** Biomacromolecules are often built by linking monomeric units through a process that removes a water molecule from between the monomers (see Figure 1.9). If one ton (1000 kg) of a monomer with a molecular mass of 200 g/mol is linked into a macromolecular structure, what volume (in L) of water would be released (1 mL water = 1 g)?
- 8. Monomers and Macromolecules** Macromolecules are often formed by linking simple monomeric units through repeated chemical bonds between such monomers (see Figure 1.8). Consider the structure shown below and draw the structure of a macromolecule that could be created from this monomer based on the chemistry shown in Figure 1.8.

- 9. Solubility in Water** Calcium stearate, the calcium salt of stearic acid, is poorly soluble in water despite being an ionic compound. Explain why using your understanding of the weak forces described in Section 1.4.

Structure of calcium stearate

- 10. Interatomic Distances in Weak Forces versus Chemical Bonds** What is the distance between the centers of two carbon atoms (their limit of approach) that are interacting through van der Waals forces? What is the distance between the centers of two carbon atoms joined in a covalent bond? (See Table 1.4.) (Section 1.4)

- 11. The Strength of Weak Forces Determines the Environmental Sensitivity of Living Cells** How does the central role of weak forces in biomolecular interactions restrict living systems to a narrow range of environmental conditions? (Section 1.4)
- 12. Cells as Steady-State Systems** Describe what is meant by the phrase “cells are steady-state systems.” (Section 1.4)
- 13. The Biosynthetic Capacity of Cells** The nutritional requirements of *Escherichia coli* cells are far simpler than those of humans, yet the macromolecules found in bacteria are as complex as those of animals. Because bacteria can make all their essential biomolecules while subsisting on a simpler diet, do you think bacteria may have more biosynthetic capacity and thus more metabolic complexity than animals? Organize your thoughts on this question, pro and con, into a rational argument. (Section 1.5)
- 14. Cell Structure** Without consulting the figures in this chapter, sketch the characteristic prokaryotic and eukaryotic cell types and label their organelles and membranes. (Section 1.5)
- 15. The Dimensions of Prokaryotic Cells and Their Constituents** *Escherichia coli* cells are about 2 μm long and 0.8 μm in diameter. (Section 1.5)
- How many *E. coli* cells laid end to end would fit across the diameter of a pinhead? (Assume a pinhead diameter of 0.5 mm.)
 - What is the volume of an *E. coli* cell? (Assume it is a cylinder, with the volume of a cylinder given by $V = \pi r^2 h$, where $\pi = 3.14$.)
 - What is the surface area of an *E. coli* cell? What is the surface-to-volume ratio of an *E. coli* cell?
 - Glucose, a major energy-yielding nutrient, is present in bacterial cells at a concentration of about 1 mM.
What is the concentration of glucose, expressed as mg/mL?
How many glucose molecules are contained in a typical *E. coli* cell? (Recall that Avogadro's number = 6.023×10^{23} .)
 - A number of regulatory proteins are present in *E. coli* at only one or two molecules per cell. If we assume that an *E. coli* cell contains just one molecule of a particular protein, what is the molar concentration of this protein in the cell?
If the molecular weight of this protein is 40 kDa, what is its concentration, expressed as mg/mL?
 - An *E. coli* cell contains about 15,000 ribosomes, supramolecular complexes that carry out protein synthesis. Assuming ribosomes are spherical and have a diameter of 20 nm (nanometers), what fraction of the *E. coli* cell volume is occupied by ribosomes?
 - The *E. coli* chromosome is a single DNA molecule whose mass is about 3×10^9 Da. This macromolecule is actually a linear array of nucleotide pairs. The average molecular weight of a nucleotide pair is 660, and each pair imparts 0.34 nm to the length of the DNA molecule. What is the total length of the *E. coli* chromosome?
How does this length compare with the overall dimensions of an *E. coli* cell?
How many nucleotide pairs does this DNA contain?
 - The average *E. coli* protein is a linear chain of 360 amino acids. If three nucleotide pairs in a gene encode one amino acid in a protein, how many different proteins can the *E. coli* chromosome encode? (The answer to this question is a reasonable approximation of the maximum number of different kinds of proteins that can be expected in bacteria.)
- 16. The Dimensions of Mitochondria and Their Constituents** Assume that mitochondria are cylinders 1.5 μm in length and 0.6 μm in diameter. (Section 1.5)
- What is the volume of a single mitochondrion?
 - Oxaloacetate is an intermediate in the citric acid cycle, an important metabolic pathway localized in the mitochondria of eukaryotic cells. The concentration of oxaloacetate in mitochondria is about 0.03 mM. How many molecules of oxaloacetate are in a single mitochondrion?
- 17. The Dimensions of Eukaryotic Cells and Their Constituents** Assume that liver cells are cuboidal in shape, 20 μm on a side. (Section 1.5)
- How many liver cells laid end to end would fit across the diameter of a pinhead? (Assume a pinhead diameter of 0.5 mm.)
 - What is the volume of a liver cell?
 - What is the surface area of a liver cell?
 - What is the surface-to-volume ratio of a liver cell?
How does this compare to the surface-to-volume ratio of an *E. coli* cell? (Compare this answer with that of problem 3c.)
Cells exchange matter and communicate with the environment through their surface membranes.
What problems do cells with low surface-to-volume ratios face that cells with high surface-to-volume ratios don't face?
 - A human liver cell contains two sets of 23 chromosomes, each set being roughly equivalent in information content. The total mass of DNA contained in these 46 enormous DNA molecules is 4×10^{12} Da. If each nucleotide pair has a mass of 660 Da, what is the total number of nucleotide pairs in these 46 DNA molecules?
 - If each nucleotide pair contributes 0.34 nm to the length of DNA, what would be the total length of the 46 liver-cell DNA molecules if laid end-to-end?
How does this length compare with the overall dimensions of a liver cell?
 - The maximal information in each set of liver cell chromosomes should be related to the number of nucleotide pairs in the chromosome set's DNA. This number can be obtained by dividing the total number of nucleotide pairs just calculated by 2. What is this value?
If this information is expressed in proteins that average 400 amino acids in length and three nucleotide pairs encode one amino acid in a protein, how many different kinds of proteins might a liver cell be able to produce? (In reality, liver cell DNA encodes approximately 20,000 different proteins.)
- 18. A Simple Genome and Its Protein-Encoding Capacity** The *Mycoplasma genitalium* genome consists of 523 genes, encoding 484 proteins, in just 580,074 base pairs (see Table 1.5).
- What fraction of the *M. genitalium* genes encode proteins?
 - What do you think the other genes encode?
 - If the fraction of base pairs devoted to protein-coding genes is the same as the fraction of the total genes that they represent, what is the average number of base pairs per protein-coding gene?
 - If it takes three base pairs to specify an amino acid in a protein, how many amino acids are found in the average *M. genitalium* protein?
 - If each amino acid contributes, on average, 120 Da to the mass of a protein, what is the mass of an average *M. genitalium* protein? (Section 1.5)
- 19. An Estimation of Minimal Genome Size for a Living Cell** One prominent study of existing cells to determine the minimum number of genes needed by a living cell has suggested that 206 genes are sufficient.
If the ratio of protein-coding genes to non-protein-coding genes is the same in this minimal organism as the genes of *Mycoplasma genitalium*, how many proteins are represented in these 206 genes?
How many base pairs would be required to form the genome of this minimal organism if the genes are the same size as *M. genitalium* genes? (Section 1.5)
- 20. An Estimation of the Number of Genes in a Virus** Virus genomes range in size from approximately 3500 nucleotides to 280,000 base pairs. The genome of SARS-CoV-2, the virus responsible for the COVID-19 pandemic, consists of 29,811 nucleotides.
If viral genes are about the same size as *M. genitalium* genes, what is the minimum and maximum number of genes in viruses? (Section 1.6)

- 21. Intracellular Protein Transport** Proteins made by ribosomes associated with the endoplasmic reticulum (ER) may pass into the ER membrane or enter the lumen of the ER. Devise pathways by which:
- a plasma membrane protein may reach the plasma membrane.
 - a protein destined for secretion is deposited outside the cell. (Section 1.5)

Think-Pair-Share Question

Create Your Own Monomer Many biopolymers are created through the repeated linking of monomeric units into a larger structure (see Figure 1.8). Such monomers have at least two functional groups that allow them to link with two other monomers. Create your own monomer with the following requirements:

- The general formula should be $C_{12}H_{17}NO_3$.
- The structure should contain one amine and one carboxylic acid functional group (see structures below).
- Every carbon should have four bonds, every oxygen two bonds, every nitrogen three bonds and every hydrogen one bond.
- Double bonds and cyclic (including aromatic) features can be present, but no triple bonds.

Water: The Medium of Life

2

If there is magic on this planet, it is contained in water.

Loren Eiseley (inscribed on the wall of the National Aquarium in Baltimore, Maryland)

◀ Where there's water, there's life.

Essential Question

Water provided conditions for the origin, evolution, and flourishing of life; water is the medium of life. **What are the properties of water that render it so suited to its role as the medium of life?**

Water is a major chemical component of Earth's surface. It is indispensable to life. Indeed, it is the only liquid that most organisms ever encounter. Life originated, evolved, and thrives in the seas. Organisms invaded and occupied terrestrial and aerial niches, but none gained true independence from water. Typically, organisms are 70% to 90% water. Indeed, normal metabolic activity can occur only when cells are at least 65% H_2O . This dependency of life on water can be understood by considering the unusual chemical and physical properties of H_2O . Subsequent chapters establish that water and its ionization products, hydrogen ions and hydroxide ions, are critical determinants of the structure and function of many biomolecules, including amino acids and proteins, nucleotides and nucleic acids, and even phospholipids and membranes. In yet another essential role, water is an indirect participant—a difference in the concentration of hydrogen ions in two solutions separated by a membrane represents an energized condition essential to the biological mechanisms of energy transformation. First, let's review the remarkable properties of water.

2.1 | What Are the Properties of Water?

Water is everywhere around us, and we are prone to take it for granted because of our familiarity with it and its bland nature. Yet we also marvel at its many unusual and fascinating properties. At the center of this fascination is the role of water as the medium of life. What are the properties of water that make it so unique to our existence?

Key Questions

- 2.1 What Are the Properties of Water?
- 2.2 What Is pH?
- 2.3 What Are Buffers, and What Do They Do?
- 2.4 What Properties of Water Give It a Unique Role in the Environment?

2.1a Water Has Unusual Properties

Compared with chemical compounds of similar atomic organization and molecular size, water displays unexpected properties. For example, compare water, the hydride of oxygen, with hydrides of oxygen's nearest neighbors in the periodic table, namely, ammonia (NH_3) and hydrogen fluoride (HF), or with H_2S , the hydride of sulfur (the next element down in Group 16 of the periodic table). Water has a substantially higher boiling point, melting point, heat of vaporization, and surface tension. Indeed, all of these physical properties are anomalously high for a substance of this molecular weight that is neither metallic nor ionic. These properties suggest that intermolecular forces of attraction between H_2O molecules are high. Thus, the internal cohesion of this substance is high. Furthermore, water has an unusually high dielectric constant, its maximum density is found in the liquid (not the solid) state, and it has a negative volume of melting (that is, the solid form, ice, occupies more space than the liquid form, water). It is truly remarkable that so many eccentric properties occur together in this single substance. As chemists, we expect to find an explanation for these apparent eccentricities in the structure of water. The key to its intermolecular attractions must lie in its atomic constitution. Indeed, *the unrivaled ability of water to form hydrogen bonds is the crucial fact to understanding its properties.*

2.1b Hydrogen Bonding in Water Is Key to Its Properties

The two hydrogen atoms of water are linked covalently to oxygen, each sharing an electron pair, to give a nonlinear arrangement (Figure 2.1). This “bent” structure of the H_2O molecule has enormous influence on its properties. If H_2O molecules were linear, it would be a nonpolar substance. In the bent configuration, however, the electronegative O atom and the two H atoms form a dipole that renders the molecule distinctly polar. Furthermore, this structure is ideally suited to H-bond formation, where water can serve as both an H donor and an H acceptor. The potential to form four H bonds per water molecule is the source of the strong intermolecular attractions that endow this substance with its anomalously high boiling point, melting point, heat of vaporization, and surface tension. In ordinary ice, the common crystalline form of water, each H_2O molecule has four nearest neighbors to which it is hydrogen bonded: Each H atom donates an H bond to the O of a neighbor, and the O atom serves as an H-bond acceptor from H atoms bound to two different water molecules (Figure 2.2). A local tetrahedral symmetry results.

Hydrogen bonding in water is cooperative. That is, an H-bonded water molecule serving as an acceptor is a better H-bond donor than an unbonded molecule (and an H_2O molecule serving as an H-bond donor becomes a better H-bond acceptor). Thus, participation in H bonding by H_2O molecules is a phenomenon of mutual reinforcement. The H bonds between neighboring molecules are weak (23 kJ/mol each) relative to the H—O covalent bonds (420 kJ/mol). As a consequence, the hydrogen atoms are situated asymmetrically between the two oxygen atoms along the O—O axis. There is never any ambiguity about which O atom the H atom is chemically bound to, nor to which O it is H bonded.

Figure 2.1 The structure of water. Two lobes of negative charge formed by the lone-pair electrons of the oxygen atom lie above and below the plane of the diagram. This electron density contributes substantially to the large dipole moment of the water molecule. Note that the H—O—H angle is 104.3° , not 109° , the angular value found in molecules with tetrahedral symmetry, such as CH_4 . Many of the important properties of water derive from this angular value, such as the decreased density of its crystalline state, ice.

2.1c The Structure of Ice Is Based on H-Bond Formation

In ice, the hydrogen bonds form a space-filling, three-dimensional network. These bonds are directional and straight; that is, the H atom lies on a direct line between the two O atoms. This linearity and directionality mean that the H bonds in ice are strong. In addition, the directional preference of the H bonds leads to an open lattice structure. For example, if the water molecules are approximated as rigid spheres centered at the positions of the O atoms in the lattice, then the observed density of ice is actually only 57% of that expected for a tightly packed arrangement of such spheres (Figure 2.2). The H bonds in ice hold the water molecules apart. Melting involves

Figure 2.2 The structure of ice. The smallest number of H_2O molecules in any closed circuit of H-bonded molecules is six, so this structure bears the name hexagonal ice.

breaking some of the H bonds that maintain the crystal structure of ice so that the molecules of water (now liquid) can pack closer together. Thus, the density of liquid water is slightly greater than that of ice. Ice floats, a property of great importance to aquatic organisms in cold climates.

In liquid water, the rigidity of ice is replaced by fluidity and the crystalline periodicity of ice gives way to spatial homogeneity. The H_2O molecules in liquid water form a disordered H-bonded network, with each molecule having an average of 4.4 close neighbors situated within a center-to-center distance of 0.284 nm (2.84 Å). At least half of the H bonds have nonideal orientations (that is, they are not perfectly straight); consequently, liquid H_2O lacks the regular lattice-like structure of ice. The space about an O atom is not defined by the presence of four H atoms but can be occupied by other H_2O molecules randomly oriented so that the local environment, over time, is essentially uniform. Nevertheless, the heat of melting for ice is but a small fraction (13%) of the heat of sublimation for ice (the energy needed to go from the solid to the vapor state). This fact indicates that the majority of H bonds between H_2O molecules survive the transition from solid to liquid. At 10°C, 2.3 H bonds per H_2O molecule remain and the tetrahedral bond order persists, even though substantial disorder is now present.

2.1d Molecular Interactions in Liquid Water Are Based on H Bonds

Water structure at the molecular level is, at any instant, inhomogeneous, consisting of local fluctuations between patches of near-tetrahedral, ordered arrays of water molecules and more asymmetrical ensembles of H_2O molecules linked together through distorted H bonds. The participation of each H_2O molecule in an average state of H bonding to its neighbors means that each molecule is connected to every other in a fluid network of H bonds. The average lifetime of an H-bonded connection between two H_2O molecules in water is 9.5 psec (picoseconds, where 1 psec = 10^{-12} sec). Thus, about every 10 psec, the average H_2O molecule moves, reorients, and interacts with new neighbors, as illustrated in Figure 2.3.

In summary, pure liquid water consists of H_2O molecules held in a disordered, three-dimensional network that has a local preference for tetrahedral geometry, yet contains a large number of strained or broken hydrogen bonds. The presence of strain creates a kinetic situation in which H_2O molecules can switch H-bond allegiances; fluidity ensues.

Figure 2.3 The fluid network of H bonds linking water molecules in the liquid state. Yellow flashes indicate H bonds breaking. It is revealing to note that, in 10 psec, a photon of light (which travels at 3×10^8 m/sec) would move a distance of only 0.003 m.

Careers in Chemistry

Kilan C. Ashad-Bishop

Kilan C. Ashad-Bishop is a biomedical scientist and advocate at Sylvester Comprehensive Cancer Center based at the University of Miami where she investigates the Social Determinants of Health, known as SDOH. The study of SDOH includes complex social factors like the effects that income, housing, education, and systemic racism have on an individual's overall health risks and their outcomes. Specifically, she uses her expertise in cancer biology to study the relationship between SDOH and the development and prognosis of chronic conditions such as cancer. Her research includes studies of molecules such as cortisol that create biochemical responses to chronic stress.

Dr. Ashad-Bishop started her journey into the field through a BS in Biology at Morgan State University and a PhD in Cancer Biology at the University of Miami Miller School of Medicine. After her graduate studies she worked as a Medical Science Consultant to translate complicated drug mechanisms of action into easily understandable narratives.

Her unique journey gives her the insight she needs to study important connections between biological health and social stress factors. Most recently she became director of National STEAM Academy to develop programs for foster youth in STEAM subjects with a social justice lens.

2.1e The Solvent Properties of Water Derive from Its Polar Nature

Because of its highly polar nature, water is an excellent solvent for ionic substances such as salts; nonionic but polar substances such as sugars, simple alcohols, and amines; and carbonyl-containing molecules such as aldehydes and ketones. Although the electrostatic attractions between the positive and negative ions in the crystal lattice of a salt are very strong, water readily dissolves salts. For example, sodium chloride (NaCl) is dissolved because dipolar water molecules participate in strong electrostatic interactions with the Na^+ and Cl^- ions, leading to the formation of **hydration shells** surrounding these ions (Figure 2.4). Although hydration shells are stable structures, they are also dynamic. Each H_2O molecule in the inner hydration shell around a Na^+ ion is replaced, on average, every 2 to 4 nsec (nanoseconds, where $1 \text{ nsec} = 10^{-9} \text{ sec}$) by another H_2O . Consequently, a water molecule is trapped only several hundred times longer by the electrostatic force field of an ion than it is by the H-bonded network of water. (Recall that the average lifetime of H bonds between water molecules is about 10 psec.)

Water Has a High Dielectric Constant The attractions between the water molecules interacting with, or **hydrating**, ions are much greater than the tendency of oppositely charged ions to attract one another. Water's ability to surround ions in dipole interactions and diminish their attraction for each other is a measure of its **dielectric constant**, D . Indeed, ionization in solution depends on the dielectric constant of the solvent; otherwise, the strongly attracted positive and negative ions would unite to form neutral molecules.

Figure 2.4 Hydration shells surrounding ions in solution. Water molecules orient so that the electrical charge on the ion is sequestered by the water dipole.

The strength of the dielectric constant is related to the force, F , experienced between two ions of opposite charge separated by a distance, r , as given in the relationship

$$F = e_1 e_2 / Dr^2$$

where e_1 and e_2 are the charges on the two ions. Table 2.1 lists the dielectric constants of some common liquids. Note that the dielectric constant for water is more than twice that of methanol and more than 40 times that of hexane.

Water Forms H Bonds with Polar Solutes In the case of nonionic but polar compounds such as sugars, the excellent solvent properties of water stem from its ability to readily form hydrogen bonds with the polar functional groups on these compounds, such as hydroxyls, amines, and carbonyls (see Figure 1.13). These polar interactions between solvent and solute are stronger than the intermolecular attractions between solute molecules caused by van der Waals forces and weaker H bonding. Thus, the solute molecules readily dissolve in water.

Hydrophobic Interactions The behavior of water toward nonpolar solutes is different from the interactions just discussed. Nonpolar solutes (or nonpolar groups on biological macromolecules) do not readily H bond to H_2O , and as a result, such compounds tend to be only sparingly soluble in water. The process of dissolving such substances is accompanied by significant reorganization of the water surrounding the solute so that the response of the solvent water to such solutes can be equated to “structure making.” Because nonpolar solutes must occupy space, the random H-bonded network of water must reorganize to accommodate them. At the same time, the H_2O molecules participate in as many H-bonded interactions with one another as the temperature permits. Consequently, the H-bonded water network rearranges toward formation of a local cage-like (**clathrate**) structure surrounding each solute molecule, as shown for a long-chain fatty acid in Figure 2.5. This fixed orientation of water molecules around a hydrophobic molecule results in a hydration shell. A major consequence of this rearrangement is that the molecules of H_2O participating in the cage layer have markedly reduced options for orientation in three-dimensional space. Water molecules tend to straddle the nonpolar molecule such that two or three tetrahedral directions (H-bonding vectors) are tangential to the space occupied by the inert solute. “Straddling” allows the water molecules to retain their H-bonding possibilities because no H-bond donor or acceptor of the H_2O is directed toward the caged solute. The H_2O molecules forming these clathrates are involved in highly ordered structures. That is, clathrate formation is accompanied by significant ordering of structure, or negative entropy.

As discussed in Section 1.4h, multiple nonpolar molecules tend to cluster together, because their joint solvation cage involves less total surface area and thus fewer ordered H_2O

Table 2.1 Dielectric Constants* of Some Common Solvents at 25°C

Solvent	Dielectric Constant (D)
Formamide	109
Water	78.5
Methyl alcohol	32.6
Ethyl alcohol	24.3
Acetone	20.7
Acetic acid	6.2
Chloroform	5.0
Benzene	2.3
Hexane	1.9

*The dielectric constant is also referred to as *relative permittivity* by physical chemists.

Figure 2.5 Nonpolar molecules create structural order in water. (*left*) Disordered network of H-bonded water molecules. (*right*) Clathrate cage of ordered, H-bonded water molecules around a nonpolar molecule.

Figure 2.6 Hydrophobic interactions between nonpolar molecules (or nonpolar regions of molecules) are caused by the increase in entropy of solvent water molecules. Note that many water molecules are freed from ordered interactions around nonpolar molecules when the nonpolar molecules coalesce. The entropy of the water has increased.

molecules than in their separate cages. It is as if the nonpolar molecules had some net attraction for one another. This apparent affinity of nonpolar structures for one another is called **hydrophobic interactions** (Figure 2.6). In actuality, the “attraction” between nonpolar solutes is an entropy-driven process due to a net decrease in order among the H_2O molecules. To be specific, hydrophobic interactions between nonpolar molecules are maintained not so much by direct interactions between the inert solutes themselves as by the increase in entropy when the water cages coalesce and reorganize. Because interactions between nonpolar solute molecules and the water surrounding them are of uncertain stoichiometry and do not share the equality of atom-to-atom participation implicit in chemical bonding, the term *hydrophobic interaction* is more correct than the misleading expression *hydrophobic bond*.

Amphiphilic Molecules Compounds containing both strongly polar and strongly nonpolar groups are called **amphiphilic molecules** (from the Greek *amphi* meaning “both” and *philos* meaning “loving”). Such compounds are also referred to as **amphipathic molecules** (from the Greek *pathos* meaning “passion”). Salts of fatty acids are a typical example that has biological relevance. They have a long, nonpolar hydrocarbon tail and a strongly polar carboxyl head group, as in the sodium salt of palmitic acid (Figure 2.7). Their behavior in aqueous solution reflects the combination of the contrasting polar and nonpolar nature of these substances. The ionic carboxylate function hydrates readily, whereas the long hydrophobic tail is intrinsically insoluble. Nevertheless, sodium palmitate and other amphiphilic molecules readily disperse in water because the hydrocarbon tails of these substances are joined together in hydrophobic interactions as their polar carboxylate functions are hydrated in a typical hydrophilic fashion. Such clusters of amphipathic molecules are termed **micelles**; Figure 2.7b is a two-dimensional representation of a spherical micelle.

Solutes Impose Order on Water Molecules The presence of dissolved substances disturbs the structure of liquid water, thereby changing its properties. The dynamic H-bonding interactions of H_2O must now accommodate the intruding substance. The net effect is that solutes, regardless of whether they are polar or nonpolar, fix nearby water molecules in a more ordered array. Ions, by establishing hydration shells through interactions with the H_2O dipoles, create local order. Hydrophobic substances, for different reasons, make structures within water. To put it another way, by limiting the orientations that neighboring water molecules can assume, solutes give order to the solvent and diminish the dynamic interplay among H_2O molecules that occurs in pure water.

Colligative Properties This influence of the solute on water is reflected in a set of characteristic changes in behavior termed **colligative properties** (properties related by a common principle). These alterations in solvent properties are related in that they all depend only on the number of solute particles per unit volume of solvent and not on the chemical nature of the solute. These effects include freezing point depression, boiling point elevation, vapor pressure lowering, and osmotic pressure effects. For example, 1 mol of an ideal solute dissolved in 1000 g of water (a 1 *m*, or molal, solution) at 1 atm depresses the freezing point by 1.86°C , raises the boiling point by 0.543°C , lowers the vapor pressure in a temperature-dependent manner, and yields a solution whose osmotic pressure relative to pure water is 22.4 atm (at 25°C). In effect, by imposing local order on the H_2O molecules, solutes make it more difficult for water to assume its crystalline lattice (freeze) or escape into the atmosphere (boil or vaporize).

Furthermore, the fourth colligative property, **osmotic pressure**, is of vital importance to biological systems. When a solution (such as the 1 *m* solution discussed here) is separated from a volume of pure water by a semipermeable membrane, the solution draws water molecules across this barrier. The H_2O molecules are moving from a region of higher effective concentration (pure H_2O) to a region of lower effective concentration (the solution). This movement of water into the solution dilutes the effects of the solute that is present. The osmotic force exerted by each mole of solute is so strong that it requires the imposition of 22.4 atm of pressure to be negated (Figure 2.8). Osmotic pressure from high concentrations of dissolved solutes is a challenge for cells. Bacterial and plant cells have strong, rigid cell walls to contain these pressures. In contrast, animal cells are bathed in extracellular fluids of comparable osmolarity, so that no net osmotic gradient exists. Also, to minimize the osmotic pressure created by the contents of their cytosol, cells tend to store substances such as amino acids and sugars in polymeric form. For example, a molecule of glycogen or starch containing 1000 glucose units exerts only 1/1000 the osmotic pressure that 1000 free glucose molecules would.

Figure 2.8 The osmotic pressure of a 1 molal (*m*) solution is equal to 22.4 atmospheres of pressure. **(a)** If a nonpermeant solute is separated from pure water by a semipermeable membrane through which H_2O passes through freely, **(b)** water molecules enter the solution (osmosis) and the height of the solution column in the tube rises. The pressure necessary to push water back through the membrane at a rate exactly the water influx is the osmotic pressure of the solution. **(c)** For a 1 *m* solution, this force is equal to 22.4 atm of pressure. Osmotic pressure is directly proportional to the concentration of the nonpermeant solute.

Figure 2.7 Amphiphilic molecules can form micelles in water. **(a)** An amphiphilic molecule: sodium palmitate. **(b)** Micelle formation by amphiphilic molecules in an aqueous solution. Because of their negatively charged surfaces, neighboring micelles repel one another and thereby maintain relative stability in solution.

Figure 2.9 The ionization of water.

2.1f Water Can Ionize to Form H^+ and OH^-

Water shows a small but finite tendency to form ions. This tendency is demonstrated by the electrical conductivity of pure water, a property that clearly establishes the presence of charged species (ions). Water ionizes because the larger, strongly electronegative O atom strips the electron from one of its hydrogen atoms, leaving the proton to dissociate (Figure 2.9):

Two ions are thus formed: protons or **hydrogen ions**, H^+ ; and **hydroxyl ions**, OH^- . Free protons are immediately hydrated to form **hydronium ions**, H_3O^+ :

Indeed, because most hydrogen atoms in liquid water are H bonded to a neighboring H_2O molecule, this protonic hydration is an instantaneous process, and the ion products of water are H_3O^+ and OH^- :

The amount of H_3O^+ or OH^- in 1 L (liter) of pure water at 25°C is 1×10^{-7} mol; the concentrations are equal because the dissociation is stoichiometric.

Although it is important to keep in mind that the hydronium ion, a hydrated hydrogen ion, represents the true state in solution, the convention is to speak of hydrogen ion concentrations in aqueous solution, even though “naked” protons are virtually nonexistent. Indeed, H_3O^+ attracts a hydration shell by H bonding to adjacent water molecules to form an H_9O_4^+ species (Figure 2.10) and even more highly hydrated forms. Similarly, the hydroxyl ion, like all other highly charged species, is also hydrated.

Figure 2.10 The hydration of H_3O^+ .

K_w is the Ion Product of Water The dissociation of water into hydrogen ions and hydroxyl ions occurs to the extent that 10^{-7} mol of H^+ and 10^{-7} mol of OH^- are present at equilibrium in 1 L of water at 25°C .

The equilibrium constant for this process is

$$K_{\text{eq}} = \frac{[\text{H}^+][\text{OH}^-]}{[\text{H}_2\text{O}]}$$

where brackets denote concentrations in moles per liter. Because the concentration of H_2O in 1 L of pure water is equal to the number of grams in a liter divided by the gram molecular weight of H_2O , or $1000/18$, the molar concentration of H_2O in pure water is 55.5 M (molar). The decrease in H_2O concentration as a result of ion formation ($[\text{H}^+]$, $[\text{OH}^-] = 10^{-7} \text{ M}$) is negligible in comparison; thus, its influence on the overall concentration of H_2O can be ignored. Thus,

$$K_{\text{eq}} = \frac{(10^{-7})(10^{-7})}{55.5} = 1.8 \times 10^{-16} \text{ M}$$

Because the concentration of H_2O in pure water is essentially constant, a new constant, **K_w** , the **ion product of water**, can be written as

$$K_w = 55.5 K_{\text{eq}} = 10^{-14} \text{ M}^2 = [\text{H}^+][\text{OH}^-]$$

This equation has the virtue of revealing the reciprocal relationship between H^+ and OH^- concentrations in aqueous solutions. If a solution is acidic (that is, it has

a significant $[H^+]$, then the ion product of water dictates that the OH^- concentration is correspondingly less. For example, if $[H^+]$ is $10^{-2} M$, $[OH^-]$ must be $10^{-12} M$ ($K_w = 10^{-14} M^2 = [10^{-2}][OH^-]$; $[OH^-] = 10^{-12} M$). Similarly, in an alkaline, or basic, solution in which $[OH^-]$ is great, $[H^+]$ is low.

2.2 | What Is pH?

To avoid the cumbersome use of negative exponents to express concentrations that range over 14 orders of magnitude, Søren Sørensen, a Danish biochemist, devised the **pH scale** by defining **pH** as *the negative logarithm of the hydrogen ion concentration*¹:

$$pH = -\log_{10} [H^+]$$

Table 2.2 gives the pH scale. Note again the reciprocal relationship between $[H^+]$ and $[OH^-]$. Also, because the pH scale is based on negative logarithms, low pH values represent the highest H^+ concentrations (and the lowest OH^- concentrations, as K_w specifies). Note also that

$$pK_w = pH + pOH = 14$$

The pH scale is widely used in biological applications because hydrogen ion concentrations in biological fluids are very low, about $10^{-7} M$ or $0.0000001 M$, a value more easily represented as pH 7. The pH of blood plasma, for example, is 7.4, or $0.00000004 M H^+$. Certain disease conditions may lower the plasma pH level to 6.8 or less, a situation that may result in death.

Table 2.2 pH Scale

The hydrogen ion and hydroxyl ion concentrations are given in moles per liter at 25°C.

pH	$[H^+]$	$[OH^-]$
0	(10^0) 1.0	0.00000000000001 (10^{-14})
1	(10^{-1}) 0.1	0.00000000000001 (10^{-13})
2	(10^{-2}) 0.01	0.00000000000001 (10^{-12})
3	(10^{-3}) 0.001	0.00000000000001 (10^{-11})
4	(10^{-4}) 0.0001	0.00000000000001 (10^{-10})
5	(10^{-5}) 0.00001	0.00000000000001 (10^{-9})
6	(10^{-6}) 0.000001	0.00000000000001 (10^{-8})
7	(10^{-7}) 0.0000001	0.0000001 (10^{-7})
8	(10^{-8}) 0.00000001	0.0000001 (10^{-6})
9	(10^{-9}) 0.000000001	0.000001 (10^{-5})
10	(10^{-10}) 0.0000000001	0.0001 (10^{-4})
11	(10^{-11}) 0.00000000001	0.001 (10^{-3})
12	(10^{-12}) 0.000000000001	0.01 (10^{-2})
13	(10^{-13}) 0.00000000000001	0.1 (10^{-1})
14	(10^{-14}) 0.000000000000001	1.0 (10^0)

¹To be precise in physical chemical terms, the *activities* of the various components, *not* their molar concentrations, should be used in these equations. The activity (*a*) of a solute component is defined as the product of its molar concentration, *c*, and an *activity coefficient*, γ : $a = c\gamma$. Most biochemical work involves dilute solutions, and the use of activities instead of molar concentrations is usually neglected. However, the concentration of certain solutes may be very high in living cells.

Example
Calculating $[H^+]$ from pH

a. What is $[H^+]$ in a solution with a $pH = 6.8$?

b. How much greater is $[H^+]$ at $pH = 6.8$ versus $pH = 7.4$?

That is, what is the ratio of the H^+ concentration in a solution of $pH = 6.8$ versus a solution of $pH = 7.4$?

Answer

Step 1: Recall that the formula that relates pH and $[H^+]$ is $[H^+] = -\log_{10}pH$

a. At $pH = 6.8$, $[H^+] = -\log_{10}pH = 10^{-6.8} = 0.00000016\ M$

Step 2:

b. At $pH\ 7.4$, $[H^+] = -\log_{10}pH = 10^{-7.4} = 0.00000004\ M$

Step 3: The ratio of the H^+ concentration in a solution of $pH = 6.8$ versus a solution of $pH = 7.4$ is given by the answer in Step 1 divided by the answer in Step 2:

$$0.000000016/0.000000004 = 4$$

The $[H^+]$ is 4 times greater at $pH = 6.8$ versus $pH = 7.4$.

At pH 7, $[H^+] = [OH^-]$; that is, there is no excess acidity or basicity. The point of **neutrality** is at pH 7, and solutions with a pH of 7 are said to be at **neutral pH**. The pH values of various fluids of biological origin or relevance are given in Table 2.3. Because the pH scale is a logarithmic scale, two solutions whose pH values differ by 1 pH unit have a tenfold difference in $[H^+]$. For example, grapefruit juice, at pH 3.2, contains more than 12 times as much H^+ as orange juice, at pH 4.3.

2.2a Strong Electrolytes Dissociate Completely in Water

Substances that are almost completely dissociated to form ions in solution are called **strong electrolytes**. The term **electrolyte** describes substances capable of generating ions in solution and thereby causing an increase in the electrical conductivity of the solution. Many salts (such as NaCl and K_2SO_4) fit this category, as do strong acids (such as HCl) and strong bases (such as NaOH). Recall from general chemistry that acids are proton donors and bases are proton acceptors. In effect, the dissociation of a strong acid such as HCl in water can be treated as a proton transfer reaction between the acid HCl and the base H_2O to give the **conjugate acid** H_3O^+ and the **conjugate base** Cl^- :

The equilibrium constant for this reaction is

$$K = \frac{[H_3O^+][Cl^-]}{[H_2O][HCl]}$$

Customarily, because the term $[H_2O]$ is essentially constant in dilute aqueous solutions, it is incorporated into the equilibrium constant K to give a new term, K_a , the *acid dissociation constant*, where $K_a = K[H_2O]$. Also, the term $[H_3O^+]$ is often replaced by H^+ , such that

$$K_a = \frac{[H^+][Cl^-]}{[HCl]}$$

For HCl, the value of K_a is exceedingly large because the concentration of HCl in aqueous solution is vanishingly small. Because this is so, the pH of HCl solutions is readily calculated from the amount of HCl used to make the solution:

$$[H^+] \text{ in solution} = [HCl] \text{ added to solution}$$

Thus, a 1 *M* solution of HCl has a pH of 0; a 1 *mM* HCl solution has a pH of 3. Similarly, a 0.1 *M* NaOH solution has a pH of 13. (Because $[OH^-] = 0.1\ M$, $[H^+]$ must be $10^{-13}\ M$.) Viewing the dissociation of strong electrolytes another way, we see that the ions formed show little affinity for each other. For example, in HCl in water, Cl^- has very little affinity for H^+ :

Table 2.3 The pH of Various Common Fluids	
Fluid	pH
Household lye	13.6
Bleach	12.6
Household ammonia	11.4
Milk of magnesia	10.3
Baking soda	8.4
Seawater	7.5–8.4
Pancreatic fluid	7.8–8.0
Blood plasma	7.4
Intracellular fluids	
Liver	6.9
Muscle	6.1
Saliva	6.6
Urine	5–8
Boric acid	5.0
Beer	4.5
Orange juice	4.3
Grapefruit juice	3.2
Vinegar	2.9
Soft drinks	2.8
Lemon juice	2.3
Gastric juice	1.2–3.0
Battery acid	0.35

and in NaOH solutions, Na^+ has little affinity for OH^- . The dissociation of these substances in water is effectively complete.

2.2b Weak Electrolytes Are Substances That Dissociate Only Slightly in Water

Substances with only a slight tendency to dissociate and form ions in solution are called **weak electrolytes**. Acetic acid, CH_3COOH , is a good example:

The acid dissociation constant K_a for acetic acid is $1.74 \times 10^{-5} M$:

$$K_a = \frac{[\text{H}^+][\text{CH}_3\text{COO}^-]}{[\text{CH}_3\text{COOH}]} = 1.74 \times 10^{-5} M$$

K_a is also termed an **ionization constant** because it states the extent to which a substance forms ions in water. The relatively low value of K_a for acetic acid reveals that the unionized form, CH_3COOH , predominates over H^+ and CH_3COO^- in aqueous solutions of acetic acid. Viewed another way, CH_3COO^- , the acetate ion, has a high affinity for H^+ .

Example What is the pH of a 0.1 M solution of acetic acid? In other words, what is the final pH when 0.1 mol of acetic acid (HAc) is added to water and the volume of the solution is adjusted to equal 1 L?

Solution

Step 1: The dissociation of HAc in water can be written simply as

where Ac^- represents the acetate ion, CH_3COO^- .

And the acid dissociation constant K_a for this equilibrium is:

$$K_a = [\text{H}^+][\text{Ac}^-]/\text{HAc} = 1.74 \times 10^{-5} M$$

In solution, some amount, x , of HAc dissociates, generating x amount of Ac^- and an equal amount x of H^+ . Ionic equilibria characteristically are established very rapidly. At equilibrium, the concentration of $\text{HAc} + \text{Ac}^-$ must equal 0.1 M .

Step 2: So, $[\text{HAc}]$ can be represented in the dissociation as $(0.1 - x) M$, and $[\text{Ac}^-]$ and $[\text{H}^+]$ then both equal x molar.

$$K_a = 1.74 \times 10^{-5} M = x^2/[0.1 - x].$$

This is a quadratic equation of the form $(ax^2 + bx + c = 0)$.

Step 3: The solution to such quadratic equations is

$$x = (-b \pm \sqrt{b^2 - 4ac})/2a.$$

For $x^2 + (1.74 \times 10^{-5})x - (1.74 \times 10^{-6}) = 0$, $x = 1.319 \times 10^{-3} M = [\text{H}^+]$

Step 4: so $\text{pH} = -\log_{10}[\text{H}^+] = 2.88$.

(Note that the calculation of x can be simplified here: Because K_a is quite small, $x \ll 0.1 M$. Therefore, K_a is essentially equal to $x^2/0.1$. Thus, $x^2 = 1.74 \times 10^{-6} M^2$, So, $x = 1.32 \times 10^{-3} M$, and $\text{pH} = 2.88$.)

2.2c The Henderson–Hasselbalch Equation Describes the Dissociation of a Weak Acid in the Presence of Its Conjugate Base

Consider the ionization of a weak acid, HA, occurring with an acid dissociation constant, K_a . Then,

and

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]}$$

Rearranging this expression in terms of the parameter of interest, $[H^+]$, we have

$$[H^+] = \frac{[K_a][HA]}{[A^-]}$$

Taking the logarithm of both sides gives

$$\log [H^+] = \log K_a + \log_{10} \frac{[HA]}{[A^-]}$$

If we change the signs and define $pK_a = -\log K_a$, we have

$$pH = pK_a - \log_{10} \frac{[HA]}{[A^-]}$$

or

$$pH = pK_a + \log_{10} \frac{[A^-]}{[HA]}$$

This relationship is known as the **Henderson–Hasselbalch equation**. Thus, the pH of a solution can be calculated, provided K_a and the concentrations of the weak acid HA and its conjugate base A^- are known. Note particularly that when $[HA] = [A^-]$, $pH = pK_a$. For example, if equal volumes of 0.1 M HAc and 0.1 M sodium acetate are mixed, then

$$pH = pK_a = 4.76$$

$$pK_a = -\log K_a = -\log_{10}(1.74 \times 10^{-5}) = 4.76$$

(Sodium acetate, the sodium salt of acetic acid, is a strong electrolyte and dissociates completely in water to yield Na^+ and Ac^- .)

The Henderson–Hasselbalch equation provides a general solution to the quantitative treatment of acid–base equilibria in biological systems. Table 2.4 gives the acid dissociation constants and pK_a values for some weak electrolytes of biochemical interest.

Table 2.4 Acid Dissociation Constants and pK_a Values for Some Weak Electrolytes (at 25°C)		
Acid	K_a (M)	pK_a
HCOOH (formic acid)	1.78×10^{-4}	3.75
CH ₃ COOH (acetic acid)	1.74×10^{-5}	4.76
CH ₃ CH ₂ COOH (propionic acid)	1.35×10^{-5}	4.87
CH ₃ CHOHCOOH (lactic acid)	1.38×10^{-4}	3.86
HOOCCH ₂ CH ₂ COOH (succinic acid) pK_1^*	6.16×10^{-5}	4.21
HOOCCH ₂ CH ₂ COO [−] (succinic acid) pK_2	2.34×10^{-6}	5.63
H ₃ PO ₄ (phosphoric acid) pK_1	7.08×10^{-3}	2.15
H ₂ PO ₄ [−] (phosphoric acid) pK_2	6.31×10^{-8}	7.20
HPO ₄ ^{2−} (phosphoric acid) pK_3	3.98×10^{-13}	12.40
C ₃ N ₂ H ₅ ⁺ (imidazole)	1.02×10^{-7}	6.99
C ₆ O ₂ N ₃ H ₁₁ ⁺ (histidine–imidazole group) $pK_R^\dagger$	9.12×10^{-7}	6.04
H ₂ CO ₃ (carbonic acid) pK_1	1.70×10^{-4}	3.77
HCO ₃ [−] (bicarbonate) pK_2	5.75×10^{-11}	10.24
(HOCH ₂) ₃ CNH ₃ ⁺ (tris-hydroxymethyl aminomethane)	8.32×10^{-9}	8.07
NH ₄ ⁺ (ammonium)	5.62×10^{-10}	9.25
CH ₃ NH ₃ ⁺ (methylammonium)	2.46×10^{-11}	10.62

[Source: *CRC Handbook of Biochemistry*, Cleveland, OH: The Chemical Rubber Co., 1968.]
*The pK values listed as pK_1 , pK_2 , or pK_3 are, in actuality, pK_a values for the respective dissociations. This simplification in notation is used throughout this book.
† pK_R refers to the imidazole ionization of histidine.

Example What is the pH when 100 mL of 0.1 *N* NaOH is added to 150 mL of 0.2 *M* HAc? The pK_a for acetic acid is 4.76.

Solution

Step 1: Use the Henderson–Hasselbalch equation to solve this problem.

$$\text{pH} = pK_a + \log_{10}[\text{Ac}^-]/[\text{HAc}]$$

Step 2: The pK_a value for acetic acid is 1.74×10^{-5} *M*. The total concentration of HAc and Ac^- is given by $0.15 \text{ L}(0.2 \text{ M}) = 0.03 \text{ mol}$.

Step 3: The concentration of Ac^- will be equal to the amount of OH^- added and the concentration of HAc is equal to 0.03 mol minus the concentration of OH^- added.

Step 4: 100 mL 0.1 *N* NaOH = 0.01 mol OH^- is added, which neutralizes 0.01 mol of HAc and yields an equivalent amount of Ac^- .

So, the amount of Ac^- = 0.01 mol and the amount of HAc is 0.03 mol – 0.01 mol or 0.02 mol. $[\text{Ac}^-] = 0.01 \text{ mol}$ and $[\text{HAc}] = 0.02 \text{ mol}$

Step 5: Using these values and the Henderson–Hasselbalch equation gives

$$\text{pH} = pK_a + \log_{10}[\text{Ac}^-]/[\text{HAc}] = 4.76 + \log_{10}0.01 \text{ mol}/0.02 \text{ mol}$$

$$\text{pH} = 4.76 - \log_{10}2 = 4.46$$

2.2d Titration Curves Illustrate the Progressive Dissociation of a Weak Acid

Titration is the analytical method used to determine the amount of acid in a solution. A measured volume of the acid solution is titrated by slowly adding a solution of base, typically NaOH, of known concentration. As incremental amounts of NaOH are added, the pH of the solution is determined, and a plot of the pH of the solution versus the amount of OH^- added yields a **titration curve**. The titration curve for acetic acid is shown in Figure 2.11. In considering the progress of this titration, keep in mind two important equilibria:

As the titration begins, mostly HAc is present, plus some H^+ and Ac^- in amounts that can be calculated (see the Example in Section 2.2b). Addition of a solution of NaOH allows hydroxide ions to neutralize any H^+ present. Note that reaction (2) as written is strongly favored; its apparent equilibrium constant is greater than 10^{15} ! As H^+ is neutralized, more HAc dissociates to H^+ and Ac^- . The stoichiometry of the titration is 1:1—for each increment of OH^- added, an equal amount of the weak acid HAc is titrated. As additional NaOH is added, the pH gradually increases as Ac^- accumulates at the expense of diminishing HAc and the neutralization of H^+ . At the point where half of the HAc has been neutralized (that is, where 0.5 equivalent of OH^- has been added), the concentrations of HAc and Ac^- are equal and $\text{pH} = pK_a$ for HAc. Thus, we have an experimental method for determining the pK_a values of weak electrolytes. These pK_a values lie at the midpoint of their respective titration curves. After all of the acid has been neutralized (that is, when one equivalent of base has been added), the pH rises exponentially.

The shapes of the titration curves of weak electrolytes are identical, as Figure 2.12 reveals. Note, however, that the midpoints of the different curves vary in a way that characterizes the particular electrolytes. The pK_a for acetic acid is 4.76, the pK_a for imidazole is 6.99, and that for ammonium is 9.25. These pK_a values are directly related to the dissociation constants of these substances, or, viewed the other way, to the relative affinities of the conjugate bases for protons. Ammonia (NH_3) has a high affinity for protons compared to Ac^- ; NH_4^+ is a poor acid compared to HAc.

Figure 2.11 The titration curve for acetic acid. CH_3COOH predominates at low pH; CH_3COO^- predominates at high pH. Note that the titration curve is relatively flat at pH values near the pK_a . In other words, the pH changes relatively little as OH^- is added in this region of the titration curve.

Figure 2.12 The titration curves for several weak electrolytes: acetic acid, imidazole, and ammonium.

2.2e Phosphoric Acid Has Three Dissociable H⁺

Figure 2.13 shows the titration curve for phosphoric acid, H_3PO_4 . This substance is a polyprotic acid, meaning it has more than one dissociable proton. Indeed, it has three, and thus, three equivalents of OH^- are required to neutralize it, as Figure 2.13 shows. Note that the three dissociable H^+ are lost in discrete steps, with each dissociation showing a characteristic pK_a . Note that pK_1 occurs at $pH = 2.15$, and the concentrations of the acid H_3PO_4 and the conjugate base $H_2PO_4^-$ are equal. As the next dissociation is approached, $H_2PO_4^-$ is treated as the acid and HPO_4^{2-} is its conjugate base. Their concentrations are equal at $pH = 7.20$, so $pK_2 = 7.20$. (Note that at this point, 1.5 equivalents of OH^- have been added.) As more OH^- is added, the last dissociable hydrogen is titrated, and pK_3 occurs at $pH = 12.4$, where $[HPO_4^{2-}] = [PO_4^{3-}]$.

The shape of the titration curves for weak electrolytes has a biologically relevant property: In the region of the pK_a , pH remains relatively unaffected as increments of OH^- (or H^+) are added. The weak acid and its conjugate base are acting as a buffer.

Figure 2.13 The titration curve for phosphoric acid.

2.3 | What Are Buffers, and What Do They Do?

Buffers are solutions that tend to resist changes in their pH as acid or base is added. Typically, a buffer system is composed of a weak acid and its conjugate base. A solution of a weak acid that has a pH nearly equal to its pK_a , by definition, contains an amount of the conjugate base nearly equivalent to the weak acid. Note that in this region, the titration curve is relatively flat (Figure 2.14). Addition of H^+ , then, has little effect because it is absorbed by the following reaction:

Similarly, any increase in $[OH^-]$ is offset by the reaction

Thus, the pH remains relatively constant. The components of a buffer system are chosen such that the pK_a of the weak acid is close to the pH of interest. It is at the pK_a that the buffer system shows its greatest buffering capacity. At pH values more than 1 pH unit from the pK_a , buffer systems become ineffective because the concentration of one of the components is too low to absorb the influx of H^+ or OH^- . The molarity of a buffer is defined as the *sum* of the concentrations of the acid and conjugate base forms.

Maintenance of pH is vital to all cells. The structure, and hence the function, of proteins, nucleic acids, and many other cellular molecules depends on weak forces such as H bonds and ionic interactions, both of which can be affected by pH. Also, processes such as metabolism are dependent on the activities of enzymes; in turn, enzyme activity is markedly influenced by pH, as the graphs in Figure 2.15 show. Consequently, changes in pH would be disruptive to metabolism for reasons that become apparent in later chapters. Organisms have a variety of mechanisms to keep the pH of their intracellular and extracellular fluids essentially constant, but the primary protection against harmful pH changes is provided by buffer systems. The buffer systems employed reflect both the need for a pK_a value near pH 7 and the compatibility of the buffer components with the metabolic machinery of cells. Two buffer systems act to maintain a constant intracellular pH—the phosphate ($HPO_4^{2-}/H_2PO_4^-$) system and the histidine system. On the other hand, the pH of the extracellular fluid that bathes the cells and tissues of animals is maintained by the bicarbonate/carbonic acid (HCO_3^-/H_2CO_3) system.

Buffer action:

Figure 2.14 A buffer system consists of a weak acid, HA, and its conjugate base, A^- .

2.3a The Phosphate Buffer System Is a Major Intracellular Buffering System

The **phosphate system** serves to buffer the intracellular fluid of cells at physiological pH because its pK_2 lies near this pH value. The intracellular pH of most cells is maintained in the range between 6.9 and 7.4. Phosphate is an abundant anion in cells, both in its inorganic form and as an important functional group on organic molecules that serve as metabolites or macromolecular precursors. In both organic and inorganic forms, its characteristic pK_2 means that the ionic species present at physiological pH are sufficient to donate or accept hydrogen ions to buffer any changes in pH, as the titration curve for H_3PO_4 in Figure 2.13 reveals. For example, if the total cellular concentration of phosphate is 20 mM (millimolar) and the pH is 7.4, the distribution of the major phosphate species is given by

$$pH = pK_2 + \log_{10} \frac{[HPO_4^{2-}]}{[H_2PO_4^-]}$$

$$7.4 = 7.20 + \log_{10} \frac{[HPO_4^{2-}]}{[H_2PO_4^-]}$$

$$\frac{[HPO_4^{2-}]}{[H_2PO_4^-]} = 1.58$$

Thus, if $[HPO_4^{2-}] + [H_2PO_4^-] = 20 \text{ mM}$, then

$$[HPO_4^{2-}] = 12.25 \text{ mM} \quad \text{and} \quad [H_2PO_4^-] = 7.75 \text{ mM}$$

Figure 2.15 pH versus enzymatic activity. Note that the x -axis (pH range) is different in each graph. (a) Pepsin is a protein-digesting enzyme active in the gastric fluid. (b) Fumarase is a metabolic enzyme found in mitochondria. (c) Lysozyme digests bacterial cell walls; it is found in cells and bodily fluids.

2.3b The Imidazole Group of Histidine Also Serves as an Intracellular Buffering System

Histidine is one of the 20 naturally occurring amino acids commonly found in proteins. It possesses an imidazole group, a five-membered heterocyclic ring with two nitrogen atoms, one of whose protons easily dissociates. The pK_a for dissociation of the imidazole hydrogen of histidine is 6.04.

In cells, histidine occurs as a free amino acid, as a constituent of proteins, and as part of dipeptides in combination with other amino acids. Because the concentration of free histidine is low and its imidazole pK_a is more than 1 pH unit removed from prevailing intracellular pH, its role in intracellular buffering is minor. However, protein-bound and dipeptide histidine may be the dominant buffering system in some cells. In combination with other amino acids, as in proteins or dipeptides, the imidazole pK_a may increase substantially. For example, the imidazole pK_a is 7.04 in **anserine**, a dipeptide containing β -alanine and histidine (Figure 2.16). Thus, this pK_a is near physiological pH, and some histidine peptides are well suited for buffering at physiological pH.

2.3c The Bicarbonate Buffer System of Blood Plasma

The important buffer system of blood plasma is the bicarbonate/carbonic acid couple:

The relevant pK_a , pK_1 for carbonic acid, is 3.77 at 25°C (Table 2.4), but at 37°C, pK_1 is 3.57.) At pH 7.4, the concentration of H_2CO_3 is a minuscule fraction of the HCO_3^- concentration, as shown by.

$$\text{pH} = 7.4 = 3.57 + \log_{10}([\text{HCO}_3^-]/[\text{H}_2\text{CO}_3])$$

$$[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3] = 6761/1$$

Thus, the plasma appears to be poorly protected against an influx of OH^- ions. However, the bicarbonate buffer system works well because the critical concentration of H_2CO_3 is maintained relatively constant through equilibrium with CO_2 produced in the tissues as a major end product of metabolism as well as the availability of CO_2 in the lungs.

The hydration of CO_2 is mediated by an enzyme, carbonic anhydrase, which facilitates equilibrium by rapidly catalyzing the hydration reaction. Thus, CO_2 serves to buffer any loss of H_2CO_3 , and blood pH is effectively maintained.

Figure 2.16 Anserine (N- β -alanyl-3-methyl-L-histidine) is an important dipeptide buffer for maintaining the intracellular pH in some tissues. The structure shown is the predominant ionic species at pH 7. pK_1 (COOH) = 2.64; pK_2 (imidazole- N^+H) = 7.04; pK_3 (N^+H_3) = 9.49.

HEPES

Figure 2.17 The structure of HEPES, 4-(2-hydroxy)-1-piperazine ethane sulfonic acid, in its fully protonated form. The pK_a of the sulfonic acid group is about 3; the pK_a of the piperazine- N^+H is 7.55 at 20°C.

2.3d Buffers Useful within Physiological pH Ranges

Not many common substances have pK_a values in the range from 6 to 8. Consequently, biochemists conducting **in vitro** experiments were once limited in their choice of buffers effective at or near physiological pH. To remedy this problem, biochemists synthesized various organic compounds with pK_a values in the desirable pH = 6–8 range, and now a large selection is available. One such compound is HEPES (Figure 2.17).

In vitro Latin for “in glass”. Originally, a phrase meant to describe experiments conducted in glass test tubes. Now it refers to any experiment that is conducted with isolated cells or cell extracts. Its counterpart is “in vivo,” that is, an experiment conducted in living cells or organisms.

Example Sample Buffer Preparation Problem

Given a solution of 0.1 *M* HEPES in its fully protonated form and ready access to 0.1 *M* HCl, 0.1 *M* NaOH, and distilled water, describe the preparation of 1 L of 0.025 *M* HEPES buffer solution, pH 7.8.

Solution

Step 1: Since the desired pH is 7.8, the relevant pK_a here is 7.55, the pK_a of the piperazine- NH^+ . But the solution contains HEPES in its fully protonated form. So, the first step is to mix equal quantities of 0.1 *M* HEPES and 0.1 *M* NaOH to neutralize the sulfonic acid group and yield a solution of 0.05 *M* HEPES sulfonate.

Step 2: Now the Henderson–Hasselbalch equation can be used to determine the proper ratio of piperazine-N: to piperazine- NH^+

$$\text{pH} = pK_a + \log([\text{piperazine-N:}]/[\text{piperazine-NH}^+])$$

$$7.8 = 7.55 + \log([\text{piperazine-N:}]/[\text{piperazine-NH}^+])$$

$$0.25 = \log([\text{piperazine-N:}]/[\text{piperazine-NH}^+])$$

$$1.78 = ([\text{piperazine-N:}]/[\text{piperazine-NH}^+])$$

Step 3: The other equation needed to solve this equation is the conservation of mass. Titration does not change the total amount of piperazine species (piperazine-N: plus piperazine- N^+H), which equals 0.025 moles in 1 L.

So, in the desired 1 L of 0.025 *M* buffer solution,

$$[\text{piperazine-N:}] + [\text{piperazine-NH}^+] = 0.025 \text{ M}$$

And the amount of each can be calculated from the ratio of their concentrations (determined in *Step 2* above):

$$[\text{piperazine-NH}^+] = 0.025 \text{ M} - [\text{piperazine-N:}]$$

$$1.78 = [\text{piperazine-N:}]/(0.025 \text{ M} - [\text{piperazine-N:}])$$

$$0.0445 \text{ M} - 1.78([\text{piperazine-N:}]) = [\text{piperazine-N:}]$$

$$0.0445 \text{ M} = 2.78([\text{piperazine-N:}])$$

$$[\text{piperazine-N:}] = 0.016 \text{ M}$$

$$[\text{piperazine-NH}^+] = 0.009 \text{ M}$$

Step 4: Mix 500 mL of 0.05 *M* HEPES sulfonate with 160 mL of 0.1 *M* NaOH and add sufficient water (340 mL) to give a final volume of 1 L. Final solution is 0.025 *M* HEPES buffer, pH 7.8. Or, more directly, combine 250 mL of 0.1 *M* HEPES in its fully protonated form with 410 mL of 0.1 *M* NaOH and 340 mL H_2O to give a final solution that is 0.025 *M* HEPES buffer, pH 7.8.

Human Biochemistry

Blood pH and Respiration

Hyperventilation, defined as a breathing rate more rapid than necessary for normal CO_2 elimination from the body, can result in an inappropriately low $[\text{CO}_2(\text{g})]$ in the blood. Central nervous system disorders such as meningitis, encephalitis, or cerebral hemorrhage as well as a number of drug- or hormone-induced physiological changes, can lead to hyperventilation. As $[\text{CO}_2(\text{g})]$ drops due to excessive exhalation, $[\text{H}_2\text{CO}_3]$ in the blood plasma falls, followed by a decline in $[\text{H}^+]$ and $[\text{HCO}_3^-]$ in the blood plasma. Blood pH rises within 20 sec of the onset of hyperventilation, becoming maximal within 15 min. $[\text{H}^+]$ can change from

its normal value of 40 nM (pH = 7.4) to 18 nM (pH = 7.74). This rise in plasma pH (increase in alkalinity) is termed **respiratory alkalosis**.

Hypoventilation is the opposite of hyperventilation and is characterized by an inability to excrete CO_2 rapidly enough to meet physiological needs. Hypoventilation can be caused by narcotics, sedatives, anesthetics, and depressant drugs; diseases of the lung also lead to hypoventilation. Hypoventilation results in **respiratory acidosis**, as $\text{CO}_2(\text{g})$ accumulates, giving rise to H_2CO_3 , which dissociates to form H^+ and HCO_3^- .

2.4 | What Properties of Water Give It a Unique Role in the Environment?

The remarkable properties of water render it particularly suitable to its unique role in living processes and the environment, and its presence in abundance favors the existence of life. Let's examine water's physical and chemical properties to see the extent to which they provide conditions that are advantageous to organisms.

As a solvent, water is powerful yet innocuous. No other chemically inert solvent compares with water for the substances it can dissolve. Also, it is very important to life, in that water is a "poor" solvent for nonpolar substances. Thus, through hydrophobic interactions, lipids coalesce, membranes form, boundaries are created defining compartments, and the cellular nature of life is established. Because of its very high dielectric constant, water is a medium for ionization. Ions enrich the living environment—they enhance the variety of chemical species and they introduce an important class of chemical reactions. They provide electrical properties to solutions and therefore to organisms. Aqueous solutions are the prime source of ions.

The thermal properties of water are especially relevant to its environmental fitness. It has great power as a buffer resisting thermal (temperature) change. Its heat capacity, or specific heat (4.1840 J/g°C), is remarkably high; it is ten times greater than iron, five times greater than quartz or salt, and twice as great as hexane. Its heat of fusion is 335 J/g. Thus, at 0°C, it takes a loss of 335 J to change the state of 1 g of H_2O from liquid to solid. Its heat of vaporization (2.24 kJ/g) is exceptionally high. These thermal properties mean that it takes substantial changes in heat content to alter the temperature and especially the state of water. Water's thermal properties allow it to buffer the climate through such processes as condensation, evaporation, melting, and freezing. Furthermore, these properties allow effective temperature regulation in living organisms. For example, heat generated within an organism as a result of metabolism can be efficiently eliminated through evaporation or conduction. The thermal conductivity of water is very high compared to other liquids. The anomalous expansion of water as it cools to temperatures near its freezing point is a unique attribute of great significance to its natural fitness. As water cools, H bonding increases because the thermal motions of the molecules are lessened. H bonding tends to separate the water molecules (Figure 2.2), thus decreasing the density of water. These changes in density mean that, at temperatures below 4°C, cool water rises and, most important, ice freezes on the surface of bodies of water, forming an insulating layer that protects the liquid water underneath.

Water has the highest surface tension (75 dyne/cm) of all common liquids (except mercury). Together, surface tension and density determine how high a liquid rises in a capillary system. Capillary movement of water plays a prominent role in the life of plants. Last, consider osmosis as it relates to water and, in particular, the bulk movement of water in the direction from a dilute aqueous solution to a more concentrated one across a semipermeable boundary. Such bulk movements determine the shape and form of living things.

Water is truly a crucial determinant of the fitness of the environment. In a very real sense, organisms are aqueous systems in a watery world.

Foundational Biochemistry Things You Should Know after Reading Chapter 2.

- Water has unusual properties, and H bonding between water molecules is the key to understanding these properties.
- Water is an excellent solvent because of its polar nature.
- Hydrophobic interactions between nonpolar molecules in aqueous solutions occur because of an entropy-driven process based on a net decrease in order among water molecules.
- Amphiphilic molecules have both polar and nonpolar chemical groupings.
- Solute molecules affect the properties of the solution through their interactions with water molecules.
- Colligative properties are properties that depend on the number of solute molecules in a solvent, not the particular chemical properties of the solute molecules.
- Water can ionize to a small but finite extent to form H^+ and OH^- ions.
- The ion product of water, K_w , is given by $K_w = [\text{H}^+][\text{OH}^-]$. $K_w = 10^{-14} \text{ M}^2$ at 25°C .
- pH is defined as the negative logarithm (to the base 10) of the H^+ concentration.
- Strong electrolytes are substances that dissociate completely in water to form ions.
- Strong electrolytes include strong acids, strong bases, and many salts, including the salts of weak acids.
- Weak electrolytes show only a slight tendency to dissociate in water and form ions.
- The ionization constant, K_a , is a measure of the extent to which a substance forms ions in solution.
- The Henderson–Hasselbalch equation relates pH to the $\text{p}K_a$ of a weak acid, as determined by the relative concentrations of the weak acid and its conjugate base.
- Titration curves can be used to determine the $\text{p}K_a$ values of weak electrolytes.
- Buffers are solutions containing amounts of a weak acid and its conjugate base sufficient to resist large changes in pH when acid or base is added.
- The phosphate buffer system is a major intracellular buffer system.
- The imidazole group of histidine can also serve as an intracellular buffer.
- The bicarbonate/carbonic acid system is the major buffering system of blood plasma and other extracellular fluids.
- Not many naturally occurring substances have $\text{p}K_a$ values in the neutral pH range, so biochemists have synthesized new compounds with such properties for in vitro work.
- The properties of water give it a significant role in the environment. The fitness of the environment for living systems depends on the properties of water.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Calculating pH from $[\text{H}^+]$** Calculate the pH of the following.
 - $5 \times 10^{-4} \text{ M HCl}$
 - $7 \times 10^{-5} \text{ M NaOH}$
 - $2 \mu\text{M HCl}$
 - $3 \times 10^{-2} \text{ M KOH}$
 - 0.04 mM HCl
 - $6 \times 10^{-9} \text{ M HCl}$
- Calculating $[\text{H}^+]$ from pH** Calculate the following from the pH values given in Table 2.3.
 - $[\text{H}^+]$ in vinegar
 - $[\text{H}^+]$ in saliva
 - $[\text{H}^+]$ in household ammonia
 - $[\text{OH}^-]$ in milk of magnesia
 - $[\text{OH}^-]$ in beer
 - $[\text{H}^+]$ inside a liver cell
- Henderson–Hasselbalch Equation and Ionization** Consider the following equilibrium.

A scientist claims that at $\text{pH}=7.0$, a solution of this compound would contain about 90% of the species in the charged form ($-\text{NH}_3^+$) and about 10% of the species in the uncharged form ($-\text{NH}_2$). Is this scientist correct? If not, provide the correct percentages for these two species in the solution.

- Effect of pH on Secondary Interactions** Three organic compounds are shown. Based upon the list of acidic compounds in Table 2.4, determine which of these molecules is/are acidic.

- Effect of Solvent on Acidity** The $\text{p}K_a$ values that are typically discussed are only applicable in water. If an acidic compound is dissolved in an organic solvent (like liquid hexane, C_6H_{14}), would this decrease or increase the acid's $\text{p}K_a$ value? Explain.
- Calculating $[\text{H}^+]$ and $\text{p}K_a$ from the pH of a Solution of Weak Acid** The pH of a 0.02 M solution of an acid was measured at 4.6.
 - What is the $[\text{H}^+]$ in this solution?
 - Calculate the acid dissociation constant K_a and $\text{p}K_a$ for this acid.
- Calculating the pH of a Solution of a Weak Acid; Calculating the pH of the Solution after the Addition of Strong Base** The K_a for formic acid is $1.78 \times 10^{-4} \text{ M}$.
 - What is the pH of a 0.1 M solution of formic acid?
 - 150 mL of 0.1 M NaOH is added to 200 mL of 0.1 M formic acid, and water is added to give a final volume of 1 L . What is the pH of the final solution?
- Prepare a Buffer by Combining a Solution of Weak Acid with a Solution of the Salt of the Weak Acid** Given 0.1 M solutions of acetic acid and sodium acetate, describe the preparation of 1 L of 0.1 M acetate buffer at a pH of 5.4.

9. Calculate the pH in a Muscle Cell from the $\text{HPO}_4^{2-}/\text{H}_2\text{PO}_4^-$ Ratio

If the internal pH of a muscle cell is 6.8, what is the $[\text{HPO}_4^{2-}]/[\text{H}_2\text{PO}_4^-]$ ratio in this cell?

10. Preparing a Phosphate Buffer Solution of pH 7.5 from Solutions of Na_3PO_4 and H_3PO_4

Given 0.1 M solutions of Na_3PO_4 and H_3PO_4 , describe the preparation of 1 L of a phosphate buffer at a pH of 7.5.

What are the molar concentrations of the ions in the final buffer solution, including Na^+ and H^+ ?

11. Polyprotic Acids: Phosphate Species Abundance at Different pHs

What are the approximate fractional concentrations of the following phosphate species at pH values of 0, 2, 4, 6, 8, 10, and 12?

- H_3PO_4
- H_2PO_4^-
- HPO_4^{2-}
- PO_4^{3-}

12. Polyprotic Acids: Citric Acid Species at Various pHs

Citric acid, a tricarboxylic acid important in intermediary metabolism, can be symbolized as H_3A . Its dissociation reactions are

If the *total* concentration of the acid and its anion forms is 0.02 M, what are the individual concentrations of H_3A , H_2A^- , HA^{2-} , and A^{3-} at pH 5.2?

13. Calculate the pH Change in a Phosphate Buffer When Acid or Base Is Added

- If 50 mL of 0.01 M HCl is added to 100 mL of 0.05 M phosphate buffer at pH 7.2, what is the resultant pH? What are the concentrations of H_2PO_4^- and HPO_4^{2-} in the final solution?
- If 50 mL of 0.01 M NaOH is added to 100 mL of 0.05 M phosphate buffer at pH 7.2, what is the resultant pH? What are the concentrations of H_2PO_4^- and HPO_4^{2-} in this final solution?

14. CO_2 Buffer System

A consequence of the condition known as COPD (chronic obstructive pulmonary disease) is the weakened capacity to exhale CO_2 that accumulates as a consequence of metabolism. This leads to an increased reabsorption of bicarbonate (HCO_3^-) into the circulation by the kidneys. Explain why this would happen.

15. Explore the Bicarbonate/Carbonic Acid Buffering System of Blood Plasma

At 37°C, if the plasma pH is 7.4 and the plasma concentration of HCO_3^- is 15 mM, what is the plasma concentration of H_2CO_3^* ? What is the plasma concentration of $\text{CO}_2(\text{dissolved})$? If metabolic activity changes the concentration of $\text{CO}_2(\text{dissolved})$ to 3 mM and $[\text{HCO}_3^-]$ remains at 15 mM, what is the pH of the plasma?

16. How to Prepare a Buffer Solution: An Anserine Buffer

Draw the titration curve for anserine (Figure 2.16). The isoelectric point of anserine is the pH where the net charge on the molecule is zero; what is the isoelectric point for anserine? Given a 0.1 M solution of anserine at its isoelectric point and ready access to 0.1 M HCl, 0.1 M NaOH, and distilled water, describe the preparation of 1 L of 0.04 M anserine buffer solution, pH 7.2.

17. On the basis of Figure 2.12, what will be the pH of the acetate–acetic acid solution when the ratio of [acetate]/[acetic acid] is 10?

- 3.76
- 4.76
- 5.76
- 11.24

18. Determination of the Molecular Weight of a Solute by Freezing Point Depression

A 100 g amount of a solute was dissolved in 1000 g of water. The freezing point of this solution was measured accurately and determined to be -1.12°C . What is the molecular weight of the solute?

19. How to Prepare a Triethanolamine Buffer

Shown here is the structure of triethanolamine in its fully protonated form:

Its $\text{p}K_a$ is 7.8. You have available at your lab bench 0.1 M solutions of HCl, NaOH, and the uncharged (free base) form of triethanolamine, as well as ample distilled water. Describe the preparation of a 1 L solution of 0.05 M triethanolamine buffer, pH 7.6.

20. How to Prepare a Tris Buffer Solution

Tris-hydroxymethyl aminomethane (Tris) is widely used for the preparation of buffers in biochemical research. Shown here is the structure of Tris in its protonated form:

Its acid dissociation constant, K_a , is 8.32×10^{-9} M. You have available at your lab bench a 0.1 M solution of Tris in its protonated form, 0.1 M solutions of HCl and NaOH, and ample distilled water. Describe the preparation of a 1-L solution of 0.02 M Tris buffer, pH 7.8.

21. Plot the Titration Curve for Bicine and Calculate How to Prepare a pH 7.5 Bicine Buffer Solution

Bicine (*N,N*-bis (2-hydroxyethyl) glycine) is another commonly used buffer in biochemistry labs. The structure of bicine in its fully protonated form is shown here:

- Draw the titration curve for bicine, assuming the $\text{p}K_a$ for its free COOH group is 2.3 and the $\text{p}K_a$ for its tertiary amino group is 8.3.
- Draw the structure of the fully deprotonated form (completely dissociated form) of bicine.
- You have available a 0.1 M solution of bicine at its isoelectric point (pH_I), 0.1 M solutions of HCl and NaOH, and ample distilled water. Describe the preparation of 1 L of 0.04 M bicine buffer, pH 7.5.
- What is the concentration of the fully protonated form of bicine in your final buffer solution?

22. Calculate the Concentration of Cl^- in Gastric Juice

Hydrochloric acid is a significant component of gastric juice. If chloride is the only anion in gastric juice, what is its concentration if $\text{pH} = 1.2$?

23. Calculate the Concentration of Lactate in Blood Plasma at pH 7.4 if [Lactic Acid] = 1.5 μM

From the $\text{p}K_a$ for lactic acid given in Table 2.4, calculate the concentration of lactate in blood plasma ($\text{pH} = 7.4$) if the concentration of lactic acid is 1.5 μM .

24. Draw the Titration Curve for a Weak Acid and Determine Its $\text{p}K_a$ from the Titration Curve

When a 0.1 M solution of a weak acid was titrated with base, the following results were obtained:

Equivalents of base added	pH observed
0.05	3.4
0.15	3.9
0.25	4.2
0.40	4.5
0.60	4.9
0.75	5.2
0.85	5.4
0.95	6.0

Plot the results of this titration and determine the pK_a of the weak acid from your graph.

- 25. Calculate the Rate of an Enzymatic Reaction Where H^+ Is a Product** The enzyme alcohol dehydrogenase catalyzes the oxidation of ethyl alcohol by NAD^+ to give acetaldehyde plus $NADH$ and a proton:

The rate of this reaction can be measured by following the change in pH. The reaction is run in 1 mL of 10 mM Tris buffer at pH 8.6. If the pH of the reaction solution falls to 8.4 after 10 minutes, what is the rate of alcohol oxidation, expressed as nanomoles of ethanol oxidized per mL per sec of reaction mixture?

- 26. The Bicarbonate Buffer System of Blood Plasma** The important buffer system of blood plasma is the bicarbonate/ carbonic acid couple:

The relevant pK_a , pK_1 for carbonic acid, is 3.77 at 25°C.

- If $[HCO_3^-] = 24 \text{ mM}$, what is $[H_2CO_3]$?
- What would be the effect on the pH of the blood plasma following a sudden influx of $4 \times 10^{-6} \text{ M OH}^-$?

However, remember that the concentration of H_2CO_3 is itself buffered by the available pools of CO_2 , which is in equilibrium with H_2CO_3 :

Under the conditions prevailing in mammalian body fluids, the equilibrium constant for this reaction, K_h is 0.003 at 37°C. That is, the equilibrium lies far to the left, such that more than 300 CO_2 molecules are present in solution for every molecule of H_2CO_3 .

$$K_h = [H_2CO_3]/[CO_2]$$

Thus,

$$[H_2CO_3] = K_h[CO_2]$$

Putting this value for $[H_2CO_3]$ into the expression for the first dissociation of H_2CO_3 gives

$$K_1 = ([H^+][HCO_3^-])/K_h[CO_2]$$

Therefore, the overall equilibrium constant for the ionization of H_2CO_3 in equilibrium with CO_2 is given by

$$K_1K_h = ([H^+][HCO_3^-])/[CO_2]$$

and K_1K_h , the product of two constants, can be defined as a new equilibrium constant, K_{overall} .

- What is the value of K_{overall} ?
- What is the value of pK_{overall} ?
- If $[CO_2] = 1.2 \text{ mM}$, what is $[HCO_3^-]$?

- 27. Blood pH and Respiration** Hyperventilation, defined as a breathing rate more rapid than necessary for normal CO_2 elimination from the body, can result in an inappropriately low $[CO_2]$ in the blood. Central nervous system disorders such as meningitis, encephalitis, or cerebral hemorrhage as well as a number of drug- or hormone-induced physiological changes, can lead to hyperventilation.

- Which component of the bicarbonate/carbonic acid buffering system will be affected first?
- What is the $[H^+]$ at pH 7.4? What is the $[H^+]$ at pH 7.74?

- 28. Hypoventilation and Blood pH** Hypoventilation is the opposite of hyperventilation and is characterized by an inability to excrete CO_2 rapidly enough to meet physiological needs. Hypoventilation can be caused by narcotics, sedatives, anesthetics, and depressant drugs; diseases of the lung also lead to hypoventilation. Which component of the bicarbonate/carbonic acid buffering system will be affected first during hypoventilation?

Think-Pair-Share Question

Titration of an Unknown Acid A 20 mL solution containing an unknown, diprotic acid (AH_2) was titrated with 0.2 M NaOH. The following figure shows the pH value of the mixture as a function of the volume (in mL) of 0.2 M NaOH added.

- Calculate the concentration of the unknown acid.
- Estimate the values of $pK_{a,1}$ and $pK_{a,2}$ for this unknown acid.

Thermodynamics of Biological Systems

3

Publiphoto/Science Source

A theory is the more impressive the greater is the simplicity of its premises, the more different are the kinds of things it relates and the more extended is its range of applicability. Therefore, the deep impression which classical thermodynamics made upon me. It is the only physical theory of universal content which I am convinced, that within the framework of applicability of its basic concepts, will never be overthrown.

Albert Einstein

▶ The sun is the source of energy for virtually all life. We even harvest its energy in the form of electricity by using windmills driven by air heated by the sun.

Essential Question

Living things require energy. Many life processes involve conversions of one kind of energy into another. To study such bioenergetic phenomena requires familiarity with thermodynamics. Thermodynamics also allows us to determine whether chemical processes and reactions occur spontaneously. **What are the laws and principles of thermodynamics that allow us to describe the flows and interchanges of heat, energy, and matter in biochemical systems?**

This chapter presents the basic thermodynamic principles underlying the concepts of heat flow, entropy, and free energy functions and the relationship between entropy and information. In addition, some related concepts are considered, including the concept of standard states, the effect of pH on standard-state free energies, the effect of concentration on the net free energy change of a reaction, and the importance of coupled processes in living things. The chapter concludes with a discussion of adenosine triphosphate (ATP) and other energy-rich compounds.

3.1 | What Are the Basic Concepts of Thermodynamics?

In any consideration of thermodynamics, a distinction must be made between the system and the surroundings. The **system** is that portion of the universe with which we are concerned. It might be a mixture of chemicals in a test tube, or a single cell, or an entire organism. The **surroundings** include everything else in the universe (Figure 3.1). The nature of the system must also be specified. There are three basic kinds of systems: isolated, closed, and open. An **isolated system** cannot exchange matter or energy with its surroundings. A **closed system** may exchange energy, but not matter, with the surroundings. An **open system** may exchange matter, energy, or both

Key Questions

- 3.1 What Are the Basic Concepts of Thermodynamics?
- 3.2 What Is the Effect of Concentration on Net Free Energy Changes?
- 3.3 How May Standard State, Equilibrium, and Cellular Conditions Be Compared?
- 3.4 What Are the Characteristics of High-Energy Biomolecules?
- 3.5 How Do Group Transfer Potentials Quantify the Reactivity of Functional Groups?
- 3.6 What Are Reduction Potentials, and How Are They Used to Account for Free Energy Changes in Redox Reactions?
- 3.7 Why Are Coupled Processes Important to Living Things?
- 3.8 What Is the Daily Human Requirement for ATP?

Isolated system:

No exchange of matter or energy

**Closed system:**

Energy exchange may occur

**Open system:**

Energy exchange and/or matter exchange may occur

Figure 3.1 The characteristics of isolated, closed, and open systems. Isolated systems exchange neither matter nor energy with their surroundings. Closed systems may exchange energy, but not matter, with their surroundings. Open systems may exchange either matter or energy with the surroundings.

with the surroundings. Living things are typically open systems that exchange matter (nutrients and waste products) and energy (heat from metabolism, for example) with their surroundings.

3.1a Three Quantities Describe the Energetics of Biochemical Reactions

The energy changes in chemical and biological reactions and processes are described by three quantities: enthalpy, entropy, and free energy:

- **Enthalpy, H** —the heat content of a system, which depends on the types and numbers of bonds in the reactants and products of a reaction. The enthalpy change, ΔH , is the heat transferred in a constant pressure process. When heat is absorbed by a system, ΔH is positive. By contrast, ΔH is negative when a process involves loss of heat by the system (transfer of heat from system to surroundings).
- **Entropy, S** —a measure of disorder or randomness in the system. An organized or ordered state is a low-entropy state, whereas a disordered state is a high-entropy state.

$$S = k \ln W \quad (3.1)$$

and

$$\Delta S = k \ln W_{\text{final}} - k \ln W_{\text{initial}} \quad (3.2)$$

where W_{final} and W_{initial} are the final and initial number of microstates, respectively, and where k is Boltzmann's constant ($k = 1.38 \times 10^{-23}$ J/K).

Entropy represents energy dispersion: *The dispersion of energy among molecular motions in discrete states (microstates)*. An increase in entropy is just an increase in the number of microstates in any macrostate. On the other hand, if only one microstate corresponds to a given macrostate, then the system has no freedom to choose its microstate—and it has zero entropy. *Entropy change measures the dispersal of energy in a process*. Dispersal of energy into a larger number of microstates results in an increase in entropy.

- **Gibbs free energy, G** —a function that describes the amount of energy that can be used to do work in a thermodynamic system. The Gibbs free energy is defined as

$$G = H - TS \quad (3.3)$$

where T is temperature in Kelvin. For any process $A \rightleftharpoons B$ at constant pressure and temperature, the free energy change, ΔG , is given by

$$\Delta G = \Delta H - T\Delta S \quad (3.4)$$

If a process results in a transfer of free energy from the system to the surroundings, it has a negative ΔG , and it is said to be **exergonic**. On the other hand, processes that transfer free energy from the surroundings to the system are said to be **endergonic** and have positive ΔG values.

All three of these quantities— H , S , and G —are **state functions**, meaning that they only depend on the state of a system, and not on how the system got there. We say that these and other state functions are **independent of path**.

Chemistry in History

Credit: The Asahi Shimbun / Contributor

Satoshi Ōmura

Satoshi Ōmura (1935–present) grew up in a poor farming community in rural Japan. As a boy he was fascinated by nature and what it could provide for humankind and other living things. His curiosity about nature led him to a career combining chemistry and pharmacology. He received a Ph.D. in Pharmaceutical Sciences from the University of Tokyo in 1968 and a Ph.D. in Chemistry at the Tokyo University of Science in 1970.

In his research, Ōmura searched for novel strains of *Streptomyces* bacteria as a source for new bioactive compounds. He isolated and cultured many thousands of microbes from soil samples in Japan and characterized their antibacterial activity.

In 1970, Ōmura isolated a strain of *Streptomyces avermitilis* from woodland soil near a golf course along the southeast coast of Honshu, Japan. Ōmura sent the bacteria to William Campbell at Merck in the U.S., who isolated avermectin and its derivative ivermectin from the bacterium. Ivermectin has been highly effective in the treatment and eradication of river blindness, lymphatic filariasis and other parasite infestations. Satoshi Ōmura and William Campbell shared in the 2015 Nobel Prize in Physiology or Medicine.

“I have long been convinced that nature has all the solutions we need to solve our past, present and future problems – we just need to find them.” Satoshi Ōmura

3.1b All Reactions and Processes Follow the Laws of Thermodynamics

Three fundamental principles—the laws of thermodynamics—govern all chemical, physical, and biological processes. The **first law of thermodynamics** states that *the total energy of an isolated system is conserved*. There are several important consequences (or alternative expressions) of this law: The total energy of the universe must be constant; and though energy may be converted from one form to another, used to do work, or moved within a system or between system and surroundings, it cannot be destroyed or created in any ordinary chemical process.

The **second law of thermodynamics** has been described and expressed in many different ways, including the following:

1. Systems tend to proceed from *ordered (low-entropy or low-probability)* states to *disordered (high-entropy or high-probability)* states.
2. The *entropy* of the system plus surroundings is unchanged by *reversible processes*; the entropy of the system plus surroundings increases for *irreversible processes*.
3. All naturally occurring processes proceed toward **equilibrium**, that is, to a state of minimum potential energy. Energy flows spontaneously so as to become diffused, dispersed, or spread out. Energy dispersal results in entropy increase.

The **third law of thermodynamics** states that *the entropy of any crystalline, perfectly ordered substance must approach zero as the temperature approaches 0 K, and, at $T = 0$ K, entropy is exactly zero*. Based on this, it is possible to establish a quantitative, absolute entropy scale for any substance as

$$S = \int_0^T C_p d \ln T \quad (3.5)$$

where C_p is the *heat capacity* at constant pressure. The heat capacity of any substance is the amount of heat 1 mole of it can store as the temperature of that substance is raised by 1 degree. For a constant pressure process, this is described mathematically as

$$C_p = \frac{dH}{dT} \quad (3.6)$$

A Deeper Look

Entropy, Information, and the Importance of “Negentropy”

When a thermodynamic system undergoes an increase in entropy, it becomes more disordered. On the other hand, a decrease in entropy reflects an increase in order. A more ordered system is more highly organized and possesses a greater information content. To appreciate the implications of decreasing the entropy of a system, consider the random collection of letters in the figure. This disorganized array of letters possesses no inherent information content, and nothing can be learned by its perusal. On the other hand, this particular array of letters can be systematically arranged to construct the first sentence of the Einstein quotation that opened this chapter: “A theory is the more impressive the greater is the simplicity of its premises, the more different are the kinds of things it relates and the more extended is its range of applicability.”

Arranged in this way, this same collection of 151 letters possesses enormous information content—the profound words of a great scientist. Just as it would have required significant effort to rearrange these 151 letters in this way, so large amounts of energy are required to construct and maintain living organisms. Energy input is required to produce information-rich, organized structures such as proteins and nucleic acids. Information content can be thought of as **negative entropy**. In 1944, Erwin Schrödinger took time out from his studies of quantum mechanics to publish a delightful book titled *What Is Life?* In it, Schrödinger wrote that negative entropy confers organization and information content to living organisms. Schrödinger pointed out that organisms must acquire negative entropy to sustain life.

French physicist Léon Brillouin later shortened the term to “negentropy.” To summarize, living systems are highly organized, low-entropy systems, far displaced from equilibrium.

If the heat capacity can be evaluated at all temperatures between 0 K and the temperature of interest, an absolute entropy can be calculated. For biological processes, *entropy changes* are more useful than absolute entropies. The entropy change for a process can be calculated if the *enthalpy change* and *free energy change* are known.

3.1c Free Energy Provides a Simple Criterion for Equilibrium

An important question for chemists, and particularly for biochemists, is, “Will the reaction proceed in the direction written?” J. Willard Gibbs, one of the founders of thermodynamics, realized that the change in the Gibbs free energy (Equation 3.4) provided an answer to this question.

If ΔG is equal to 0, the process is at *equilibrium* and there is no net flow either in the forward or reverse direction. When $\Delta G = 0$, $\Delta S = \Delta H/T$ and the enthalpic and entropic changes are exactly balanced. Any process with a nonzero ΔG proceeds spontaneously to a final state of lower free energy. If ΔG is negative, the process proceeds spontaneously in the direction written. If ΔG is positive, the reaction or process proceeds spontaneously in the reverse direction. Spontaneity is concerned only with whether the reaction is thermodynamically favorable (that is, ΔG is negative) or not. Spontaneity, in the thermodynamic sense, should not be confused with rate, a term in kinetics indicating how fast the reaction goes. If the process has a negative ΔG , it is said to be exergonic, whereas processes with positive ΔG values are endergonic. The sign and value of ΔG do not allow us to determine *how fast* the process will go.

The Standard State In order to compare the thermodynamic parameters of different reactions, it is convenient to define a *standard state*. For solutes in a solution, the standard state is normally unit activity (often simplified to 1 M concentration). Enthalpy,

entropy, and other thermodynamic quantities are often given or determined for standard-state conditions and are then denoted by a superscript degree sign °, as in ΔH° , ΔS° , and so on.

The Standard-State Free Energy Change The free energy change, ΔG , for any reaction depends upon the nature of the reactants and products, but it is also affected by the conditions of the reaction, including temperature, pressure, pH, and the concentrations of the reactants and products. As explained earlier, it is useful to define a standard state for such processes. If the free energy change for a reaction is sensitive to solution conditions, what is the particular significance of the standard-state free energy change? To answer this question, consider a reaction between two reactants A and B to produce the products C and D.

The free energy change for non-standard-state concentrations is given by

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[C][D]}{[A][B]} \right) \quad (3.8)$$

At equilibrium, $\Delta G = 0$ and $[C][D]/[A][B] = K_{eq}$. We then have

$$\Delta G^\circ = -RT \ln K_{eq} \quad (3.9)$$

or, in base 10 logarithms,

$$\Delta G^\circ = -2.3RT \log_{10} K_{eq} \quad (3.10)$$

This can be rearranged to

$$K_{eq} = 10^{-\Delta G^\circ/2.3RT} \quad (3.11)$$

In any of these forms, this relationship allows the standard-state free energy change for any process to be determined if the equilibrium constant is known. More importantly, it states that the *point of equilibrium for a reaction in solution is a function of the standard-state free energy change for the process*. That is, ΔG° is another way of writing an equilibrium constant.

Equation 3.9 has an additional meaning: ΔG° is a measure of how far a reaction is from equilibrium under standard-state conditions. If ΔG° is close to zero, the reaction is close to equilibrium under standard-state conditions. If ΔG° is large (whether positive or negative), the reaction is far from equilibrium under standard-state conditions.

3.2 | What Is the Effect of Concentration on Net Free Energy Changes?

Equation 3.8 shows that the free energy change for a reaction can be very different from the standard-state value if the concentrations of reactants and products differ significantly from unit activity.¹ The effects can often be dramatic. Consider the hydrolysis of phosphocreatine:

This reaction is strongly exergonic, and the standard-state free energy change under physiological conditions at 37°C is -42.8 kJ/mol . Physiological concentrations of phosphocreatine, creatine, and inorganic phosphate are normally between 1 and 10 mM.

¹Strictly speaking, unit activity is defined as 1 m (molal). In the dilute solutions typical of biochemical situations, molarity (M) and molality can be used interchangeably.

Assuming 1 mM concentrations and using Equation 3.8, the ΔG for the hydrolysis of phosphocreatine is

$$\Delta G = -42.8 \text{ kJ/mol} + (8.314 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \ln \left(\frac{[0.001][0.001]}{[0.001]} \right) \quad (3.13)$$

$$\Delta G = -60.5 \text{ kJ/mol} \quad (3.14)$$

At 37°C, the difference in ΔG between standard-state and 1 mM concentrations for such a reaction is thus approximately -17.7 kJ/mol .

For biochemical reactions in which hydrogen ions (H^+) are consumed or produced, the usual definition of the standard state is awkward. Standard state for the H^+ ion is 1 M, which corresponds to pH 0. At this pH, nearly all enzymes would be denatured and biological reactions would not occur. It makes more sense to use free energies and equilibrium constants determined at pH 7. Biochemists have thus adopted a modified standard state, designated with prime (') symbols, as in $\Delta G^{\circ'}$, K_{eq}' , $\Delta H^{\circ'}$, and so on. For values determined in this way, a standard state of 10^{-7} M H^+ and unit activity (1 M for solutions, 1 atm for gases and pure solids defined as unit activity) for all other components (in the ionic forms that exist at pH 7) is assumed.

3.3 How May Standard State, Equilibrium, and Cellular Conditions Be Compared?

Any biochemical reaction may be imagined to occur under several different conditions, including standard state, equilibrium, and cellular conditions. How can these various states be compared from an energetic perspective?

Consider a typical reaction—the conversion of dihydroxyacetonephosphate to glyceraldehyde-3-phosphate in glycolysis. The reaction at standard state (Figure 3.2) has a free energy change ($\Delta G^{\circ'}$) of $+7.56 \text{ kJ/mol}$. This is the free energy change when all the reactants and products are at 1 M concentration (but with $[\text{H}^+]$ at 10^{-7} M). Though important as a point of reference, such conditions never occur in any organism. Now, if the system, initially at standard state, is left alone, it will eventually reach a state of equilibrium (the left-most case in Figure 3.2). Since the $\Delta G^{\circ'}$ is positive, at equilibrium, $[\text{DHAP}] > [\text{G3P}]$. *It is valuable to appreciate that, for any reaction, the magnitude of $\Delta G^{\circ'}$ is a measure of how far standard-state conditions are from*

Figure 3.2 Comparison of standard state (*center*), equilibrium (*left*), and cellular (*right*) conditions for a typical metabolic reaction.

Example The phosphoglucoisomerase reaction in glycolysis converts glucose-6-phosphate to fructose-6-phosphate:

The ΔG° for this reaction as written above is +1.67 kJ/mol. The concentrations of glucose-6-P and fructose-6-P in human erythrocytes are 0.083 mM and 0.014 mM, respectively. What is the value of ΔG for this reaction in erythrocytes at human body temperature (310 K)?

Solution

Step 1: Set up the equation.

Using Equation 3.8:

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[\text{Fructose-6-P}]}{[\text{Glucose-6-P}]} \right)$$

Step 2: Solve for ΔG .

$$\Delta G = +1.67 \text{ kJ/mol} + (8.314 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \ln \left(\frac{0.014 \times 10^{-3} \text{ M}}{0.083 \times 10^{-3} \text{ M}} \right)$$

$$\Delta G = 1670 \text{ J/mol} + (8.314 \text{ J/mol} \cdot \text{K})(310 \text{ K})(-1.78)$$

$$\Delta G = -2917 \text{ J/mol} = -2.92 \text{ kJ/mol}$$

equilibrium! Moreover the simple relation $\Delta G^\circ = -RT \ln K_{\text{eq}}$ (Equation 3.9) is the quantitative connection between equilibrium and standard-state conditions.

In a similar manner, Equation 3.8 is the quantitative connection between standard state and actual conditions in living systems. For the present reaction, we have

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[\text{G3P}]}{[\text{DHAP}]} \right) \quad (3.15)$$

It is important to note that the concentrations in this equation are the *cellular* conditions, which are established by the many processes extant in the cell. The cell is not at equilibrium, nor is it at standard state. Importantly, the magnitude of the cellular ΔG is a measure of how far cellular conditions are from standard state. In the present case, the value of ΔG of +2.41 kJ/mol lies between those of the equilibrium and standard states.

3.4 What Are the Characteristics of High-Energy Biomolecules?

Organisms are highly organized chemical engines whose existence requires an external source of energy. Either directly or indirectly, virtually all life on earth depends on energy from the sun. Among life forms, there is a hierarchy of energetics: Certain organisms capture solar energy directly, whereas others derive their energy from this group in subsequent processes. Organisms that absorb light energy directly are called **phototrophic organisms**. These organisms store solar energy in the form of various organic molecules. Organisms that feed on these latter molecules, releasing the stored energy in a series of oxidative reactions, are called **chemotrophic organisms**. Despite these differences, both types of organisms share common mechanisms for generating a useful form of chemical energy. Once captured in chemical form, energy can be released in controlled exergonic reactions to drive a variety of life processes that require energy. A small family of universal biomolecules mediates the flow of energy from exergonic reactions to the energy-requiring processes of life. These **high-energy molecules** are compounds whose reaction with a substance normally present in the environment (for example, H_2O [hydrolysis reaction] or O_2 [oxidation reaction]) occurs with a ΔG° more negative than -25 kJ/mol . Phosphate compounds are considered high energy if they exhibit large negative free energies of hydrolysis (that is, if ΔG° is more negative than -25 kJ/mol). Oxidation of reduced coenzymes (NADH, NADPH, and FADH_2) typically occurs with a free energy change of -150 to -220 kJ/mol .

3.4a High Energy Phosphate Compounds

Table 3.1 lists the most important high-energy phosphate compounds. Such molecules include *phosphoric anhydrides* (ATP, ADP), an *enol phosphate* (PEP), *acyl phosphates* (such as acetyl phosphate), and *guanidino phosphates* (such as creatine phosphate). Also included are thioesters, such as acetyl-CoA, which do not contain phosphorus but have a large negative free energy of hydrolysis. As noted earlier, the exact amount of chemical free energy available from the hydrolysis of such compounds depends on concentration, pH, temperature, and so on, but the $\Delta G^{\circ'}$ values for hydrolysis of these substances are substantially more negative than those for most other metabolic species.

There are two important points to note here: First, high-energy phosphate compounds are not long-term energy storage substances. They are transient forms of stored energy, meant to carry energy from point to point, from one enzyme system to another, in the minute-to-minute existence of the cell. (As we shall see in subsequent chapters, other molecules bear the responsibility for long-term storage of energy supplies.) Second, the term *high-energy compound* should not be construed to imply that these molecules are unstable and hydrolyze or decompose unpredictably. ATP, for example, is quite a stable molecule. A substantial *activation energy* must be delivered to ATP to hydrolyze the terminal, or γ , phosphate group. In fact, as shown in Figure 3.3, the activation energy that must be absorbed by the molecule to break the O—P $_{\gamma}$ bond is normally 200 to 400 kJ/mol, which is substantially larger than the net 30.5 kJ/mol released in the hydrolysis reaction. The energetics of metabolism is more concerned with the *net release* of 30.5 kJ/mol than with the activation energy for the reaction (because the role of enzymes is to lower the energy of activation). The net release of large quantities of free energy distinguishes the high-energy phosphoric anhydrides from their “low-energy” ester cousins, such as glycerol-3-phosphate (Table 3.1). The next section provides a quantitative framework for understanding these comparisons.

Table 3.1 Free Energies of Hydrolysis of Some High-Energy Compounds*

Compound and Hydrolysis Reaction	$\Delta G^{\circ'}$ (kJ/mol)
Phosphoenolpyruvate $\longrightarrow$ pyruvate + P _i	−62.2
1,3-Bisphosphoglycerate $\longrightarrow$ 3-phosphoglycerate + P _i	−49.6
Creatine phosphate $\longrightarrow$ creatine + P _i	−43.3
Acetyl phosphate $\longrightarrow$ acetate + P _i	−43.3
Adenosine-5'-triphosphate $\longrightarrow$ ADP + P _i	−35.7 [†]
Adenosine-5'-triphosphate $\longrightarrow$ ADP + P _i (with excess Mg ²⁺)	−30.5
Adenosine-5'-diphosphate $\longrightarrow$ AMP + P _i	−35.7
Pyrophosphate $\longrightarrow$ P _i + P _i (in 5 mM Mg ²⁺)	−33.6
Adenosine-5'-triphosphate $\longrightarrow$ AMP + PP _i (excess Mg ²⁺)	−32.3
Uridine diphosphoglucose $\longrightarrow$ UDP + glucose	−31.9
Acetyl-coenzyme A $\longrightarrow$ acetate + CoA	−31.5
S-adenosylmethionine $\longrightarrow$ methionine + adenosine	−25.6 [‡]
Glucose-1-phosphate $\longrightarrow$ glucose + P _i	−21.0
Sn-Glycerol-3-phosphate $\longrightarrow$ glycerol + P _i	−9.2
Adenosine-5'-monophosphate $\longrightarrow$ adenosine + P _i	−9.2

Figure 3.3 The activation energies for phosphoryl group transfer reactions (200–400 kJ/mol) are substantially larger than the free energy of hydrolysis of ATP (–30.5 kJ/mol).

A Deeper Look

Why Nature Chose Phosphates

Phosphoryl transfer reactions form the heart of energy metabolism in cells, including both the formation of phosphorylated metabolites that then become substrates for energy-yielding pathways and activation of metabolites that serve as building blocks in energy-consuming biosynthetic processes. Why did these reactions based on phosphorus evolve to be so ubiquitous and important? The answer lies in two consequences of the charge-charge repulsions embodied in phosphate esters and phosphoric anhydrides. On the one hand, charge-charge repulsions between electron-rich reactants and negatively charged phosphates make phosphate esters among the most inert of common biochemical compounds. (The very high

free energy of activation for ATP hydrolysis, shown in Figure 3.3 is just one example.) On the other hand, the very same charge-charge repulsion also makes it possible to favor either phosphate ester hydrolysis or synthesis by adjusting the electrostatic environment in the active sites of enzymes mediating phosphoryl transfer reactions. This elegant capacity to adjust and regulate electrostatic effects means that phosphate esters are ideal compounds to participate in either energy-producing or energy-consuming metabolic reactions.

3.4b ATP Is an Intermediate Energy-Shuttle Molecule

One last point about Table 3.1 deserves mention. Despite the central importance of ATP as a high-energy phosphate, it holds an intermediate place in the rank of high-energy phosphates. PEP, 1,3-BPG, creatine phosphate, acetyl phosphate, and pyrophosphate all exhibit higher values of $\Delta G^{\circ'}$. This is not a biological anomaly. ATP is uniquely situated between the very-high-energy phosphates synthesized in the breakdown of fuel molecules and the numerous lower-energy acceptor molecules that are phosphorylated in the course of further metabolic reactions. ADP can accept both phosphates and energy from the higher-energy phosphates, and the ATP thus formed can donate both phosphates and energy to the lower-energy molecules of metabolism. The ATP/ADP pair is an intermediately placed acceptor/donor system among high-energy phosphates. In this context, ATP functions as a very versatile but intermediate energy-shuttle device that interacts with many different energy-coupling enzymes of metabolism.

3.4c The Hydrolysis of Phosphoric Acid Anhydrides Is Highly Favorable

ATP contains two *pyrophosphoryl* or *phosphoric acid anhydride* linkages, as shown in Figure 3.4. Other common biomolecules possessing phosphoric acid anhydride linkages include ADP, GTP, GDP, and the other nucleoside diphosphates and triphosphates, sugar nucleotides such as UDP–glucose, and inorganic pyrophosphate itself. All exhibit large negative free energies of hydrolysis, as shown in Table 3.1. Three factors, described in detail below, account for the large negative ΔG° values for the hydrolysis reactions: Destabilization of the reactant due to bond strain caused by electrostatic repulsion, stabilization of the products by ionization and resonance, and entropy factors due to hydrolysis and subsequent ionization.

Destabilization Due to Electrostatic Repulsion Electrostatic repulsion in the reactants is best understood by comparing these phosphoric anhydrides with other reactive anhydrides, such as acetic anhydride. As shown in Figure 3.5a, the electronegative carbonyl oxygen atoms withdraw electrons from the C=O bonds, producing partial negative charges on the oxygens and partial positive charges on the carbonyl carbons. Each of these electrophilic carbonyl carbons is further destabilized by the other acetyl group, which is also electron withdrawing in nature. As a result, acetic anhydride is unstable with respect to its hydrolysis products.

The situation with phosphoric anhydrides is similar. The phosphorus atoms of the pyrophosphate anion are electron withdrawing and destabilize PP_i with respect to its hydrolysis products. Furthermore, the reverse reaction, reformation of the anhydride bond from the two anionic products, requires that the electrostatic repulsion between these anions be overcome (see following).

Stabilization of Hydrolysis Products by Ionization and Resonance The pyrophosphoryl group possesses two negative charges at pH values above 7.5 or so (Figure 3.5a). The hydrolysis products, two phosphate esters, each carry about two negative charges at pH values above 7.2. The increased ionization of the hydrolysis products helps stabilize the electrophilic phosphorus nuclei.

Stabilization of the products by resonance and electrostatic effects, the second type of stabilization, is illustrated in Figure 3.5b by the reactant anhydrides. The unpaired electrons of the bridging oxygen atom in acetic anhydride (and phosphoric anhydride) cannot participate in resonance structures with both electrophilic centers at once. This **competing resonance** situation is relieved in the product acetate or phosphate molecules.

Entropy Factors Arising from Hydrolysis and Ionization For the phosphoric anhydrides, and for most of the high-energy compounds discussed here, there is an additional *entropic* contribution to the free energy of hydrolysis. Most of the hydrolysis reactions of Table 3.1 result in an increase in the number of molecules in solution.

Figure 3.4 The triphosphate chain of ATP contains two phosphoric anhydride linkages (also known as pyrophosphate linkages), both of which release large amounts of energy upon hydrolysis. The high energy bonds are emphasized with yellow shading.

(a)

Acetic anhydride:

Phosphoric anhydrides:

(b)

Competing resonance in acetic anhydride:

These can only occur alternately

Simultaneous resonance in the hydrolysis products:

These resonances can occur simultaneously

Figure 3.5 (a) Electrostatic repulsion between adjacent partial positive charges (on carbon and phosphorus, respectively) is relieved upon hydrolysis of the anhydride bonds of acetic anhydride and phosphoric anhydrides. The pink and blue shadings represent two mutually exclusive or **competing resonance** possibilities. (b) The competing resonances of acetic anhydride and the simultaneous resonance forms of the hydrolysis product, acetate.

As shown in Figure 3.6, the hydrolysis of ATP (at pH values above 7) creates three species—ADP, inorganic phosphate (P_i), and a hydrogen ion—from only two reactants (ATP and H_2O). The entropy of the solution increases because the more particles, the more disordered the system. (This effect is ionization dependent because at low pH, the hydrogen ion created in many of these reactions simply protonates one of the phosphate oxygens, and one fewer species results from the hydrolysis.)

3.4d The Hydrolysis $\Delta G^\circ'$ of ATP and ADP Is Greater Than That of AMP

The concepts of destabilization of reactants and stabilization of products described for pyrophosphate also apply to ATP and other phosphoric anhydrides (Figure 3.6). ATP and ADP are destabilized relative to the hydrolysis products by electrostatic repulsion, competing resonance, and entropy. AMP, on the other hand, is a phosphate ester (not an anhydride) possessing only a single phosphoryl group and is not markedly different from the product inorganic phosphate in terms of electrostatic repulsion and resonance stabilization. Thus, the $\Delta G^\circ'$ for hydrolysis of AMP is much smaller than the corresponding values for ATP and ADP.

3.4e Acetyl Phosphate and 1,3-Bisphosphoglycerate Are Phosphoric-Carboxylic Anhydrides

The mixed anhydrides of phosphoric and carboxylic acids, frequently called acyl phosphates, are also energy rich. Two biologically important acyl phosphates are acetyl phosphate and 1,3-bisphosphoglycerate. Hydrolysis of these species yields acetate and

Figure 3.6 Hydrolysis of ATP to ADP (and/or of ADP to AMP) leads to relief of electrostatic repulsion.

3-phosphoglycerate, respectively, in addition to inorganic phosphate (Figure 3.7). Once again, the large $\Delta G^\circ'$ values indicate that the reactants are destabilized relative to products. This arises from bond strain, which can be traced to the partial positive charges on the carbonyl carbon and phosphorus atoms of these structures. The energy stored in the mixed anhydride bond (which is required to overcome the charge-charge repulsion) is released upon hydrolysis. Increased resonance possibilities in the products relative to the reactants also contribute to the large negative $\Delta G^\circ'$ values. The value of $\Delta G^\circ'$ depends on the pK_a values of the starting anhydride and the product phosphoric and carboxylic acids as well as the pH of the medium.

3.4f Enol Phosphates Are Potent Phosphorylating Agents

The largest value of $\Delta G^\circ'$ in Table 3.1 belongs to *phosphoenolpyruvate* or *PEP*, an enolic phosphate. This molecule is an important intermediate in carbohydrate metabolism, and due to its large negative $\Delta G^\circ'$, it is a potent phosphorylating agent. PEP is formed via the dehydration of 2-phosphoglycerate by enolase during fermentation and glycolysis. PEP is subsequently transformed into pyruvate upon the transfer of its phosphate to ADP by pyruvate kinase (Figure 3.8). The very large negative value of $\Delta G^\circ'$ for the latter reaction is, to a large extent, the result, of a secondary reaction of the *enol* form of pyruvate. Upon hydrolysis, the unstable enolic form of pyruvate immediately converts to the keto form with a resulting large negative $\Delta G^\circ'$ (Figure 3.9). Together, the hydrolysis and subsequent tautomerization result in an overall $\Delta G^\circ'$ of -62.2 kJ/mol.

Acetyl phosphate

Figure 3.8 Phosphoenolpyruvate (PEP) is produced by the enolase reaction (in glycolysis) and in turn drives the phosphorylation of ADP to form ATP in the pyruvate kinase reaction.

Figure 3.9 Hydrolysis and the subsequent tautomerization account for the very large $\Delta G^{\circ'}$ of PEP.

Figure 3.10 Adenosine-5'-triphosphate (ATP). Color indicates the locations of the dissociable protons of ATP.

Figure 3.11 The pH dependence of the free energy of hydrolysis of ATP. Because pH varies only slightly in biological environments, the effect on ΔG is usually small.

3.4g The Complex Equilibria Involved in ATP Hydrolysis

So far, the hydrolyses of ATP and other high-energy phosphates have been portrayed as simple processes. The situation in a real biological system is far more complex, due to the operation of several ionic equilibria. First, ATP, ADP, and the other species in Table 3.1 can exist in several different ionization states that must be accounted for in any quantitative analysis. Second, phosphate compounds bind a variety of divalent and monovalent cations with substantial affinity, and the various metal complexes must also be considered in such analyses. Consideration of these special cases makes the quantitative analysis far more realistic. The importance of these ionic equilibria in group transfer reactions is illustrated for the hydrolysis of ATP, but the principles and methods presented are general and can be applied to any similar hydrolysis reaction.

The ΔG° of Hydrolysis for ATP Is pH-Dependent ATP has four dissociable protons, as indicated in Figure 3.10. Three of the protons on the triphosphate chain dissociate at very low pH. The last proton to dissociate from the triphosphate chain possesses a pK_a of 6.95. At higher pH values, ATP is completely deprotonated. ADP and phosphoric acid also undergo multiple ionizations. These multiple ionizations make the equilibrium constant for ATP hydrolysis more complicated than the simple expression in Equation 3.21. Multiple ionizations must also be taken into account when the pH dependence of ΔG° is considered. The calculations are beyond the scope of this text, but Figure 3.11 shows the variation of ΔG° as a function of pH. The free energy of hydrolysis is nearly constant from pH 4 to pH 6. At higher values of pH, ΔG° varies linearly with pH, becoming more negative by 5.7 kJ/mol for every pH unit of increase at 37°C. Because the pH of most biological tissues and fluids is near neutrality, the effect on ΔG° is relatively small, but it must be taken into account in certain situations.

Most biological environments contain substantial amounts of divalent and monovalent metal ions, including Mg^{2+} , Ca^{2+} , Na^+ , K^+ , and so on. In most real biological environments (with pH near 7 and Mg^{2+} concentrations of 5 mM or more), the free energy of hydrolysis of ATP is altered more by metal ions than by protons. A widely used “consensus value” for ΔG° of ATP in biological systems is **−30.5 kJ/mol** (Table 3.1). This value, cited in the 1976 *Handbook of Biochemistry and Molecular Biology* (3rd ed., *Physical and Chemical Data*, Vol. 1, pp. 296–304, Boca Raton, FL: CRC Press), was determined at 37°C in the presence of “excess Mg^{2+} .” *This is the value we use for metabolic calculations in the balance of this text.*

Concentration Affects the Free Energy of Hydrolysis of ATP Through all these calculations of the effect of pH and metal ions on the ATP hydrolysis equilibrium, we have assumed *standard conditions* with respect to concentrations of all species except for protons. The levels of ATP, ADP, and other high-energy metabolites never even begin to approach the standard state of 1 M. In most cells, the concentrations of these species are more typically 1 to 5 mM or even less. Earlier, we described the effect of concentration on equilibrium constants and free energies (Equation 3.8). For the present case, we can rewrite this as

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[\Sigma ADP][\Sigma P_i]}{[\Sigma ATP]} \right) \quad (3.16)$$

where the terms in brackets represent the sum (Σ) of the concentrations of all the ionic forms of ATP, ADP, and P_i .

It is clear that changes in the concentrations of these species can have large effects on ΔG . The concentrations of ATP, ADP, and P_i may, of course, vary in real biological environments. However, for the sake of some model calculations, we assume that all three concentrations are equal; then the effect of concentration on ΔG is as shown in Figure 3.12. The free energy of hydrolysis of ATP, which is -35.7 kJ/mol at 1 M, becomes -49.4 kJ/mol at 5 mM (that is, the concentration for which $pC = -2.3$ in Figure 3.12). At 1 mM ATP,

ADP, and P_i , the free energy change becomes even more negative at -53.6 kJ/mol. A useful approximation for the ΔG of hydrolysis under cellular conditions is -50 to -55 kJ/mol.

All the other high- and low-energy phosphates experience roughly similar changes in concentration under physiological conditions and thus similar changes in their free energies of hydrolysis. The roles of the very-high-energy phosphates (PEP, 1,3-bisphosphoglycerate, and creatine phosphate) in the synthesis and maintenance of ATP in the cell are considered in later discussions of metabolic pathways. In the meantime, several of the problems at the end of this chapter address such coupled reactions (see Section 3.7).

3.5 How Do Group Transfer Potentials Quantify the Reactivity of Functional Groups?

Many reactions in biochemistry involve the transfer of a functional group from a donor molecule to a specific receptor molecule or to water. The concept of **group transfer potential** explains the tendency for such reactions to occur. Biochemists define the group transfer potential as the free energy change that occurs upon hydrolysis, that is, upon transfer of the particular group to water. This concept and its terminology are preferable to the more qualitative notion of *high-energy bonds*.

The concept of group transfer potential has general application. Other kinds of transfer (of hydrogen ions and electrons, for example) are commonly characterized in terms of appropriate measures of transfer potential (pK_a and reduction potential, $\mathcal{E}_o$, respectively). As shown in Table 3.2, the notion of group transfer is fully analogous to those of ionization potential and reduction potential. The similarity is anything but coincidental because all of these are really specific instances of free energy changes. If we write

we do not really mean that a proton has literally been removed from the acid AH. In the gas phase at least, this would require the input of approximately 1200 kJ/mol! What we really mean is that the proton has been *transferred* to a suitable acceptor molecule, usually water:

The appropriate free energy relationship is, of course,

$$pK_a = \frac{\Delta G}{2.303 RT} \quad (3.18)$$

Similarly, the release of free energy that occurs upon the hydrolysis of ATP and other “high-energy phosphates” can be treated quantitatively in terms of *group transfer*. It is common to write for the hydrolysis of ATP

Figure 3.12 The free energy of hydrolysis of ATP as a function of concentration at 38°C, pH 7.0. The plot follows the relationship described in Equation 3.16, with the concentrations $[C]$ of ATP, ADP, and P_i assumed to be equal.

Table 3.2 Types of Transfer Potential

	Proton Potential (Acidity)	Group Transfer Potential (High-Energy Bond)	Standard Reduction Potential (Electron-Transfer Potential)
Simple equation	$AH \rightleftharpoons A^- + H^+$	$A \sim P \rightleftharpoons A + P_i$	$A \rightleftharpoons A^+ + e^-$
Equation including acceptor	$AH + H_2O \rightleftharpoons A^- + H_3O^+$	$A \sim PO_4^{2-} + H_2O \rightleftharpoons A-H + HPO_4^{2-}$	$A + H^+ \rightleftharpoons A^+ + \frac{1}{2} H_2$
Measure of transfer potential	$pK_a = \frac{\Delta G^\circ}{2.303 RT}$	$\ln K_{eq} = \frac{-\Delta G^\circ}{RT}$	$\Delta \mathcal{E}_o = \frac{-\Delta G^\circ}{n\mathcal{F}}$
Free energy change of transfer is given by:	ΔG° per mole of H^+ transferred	ΔG° per mole of phosphate transferred	ΔG° per mole of e^- transferred

[Source: Klotz, I. M., 1986. *Introduction to Biomolecular Energetics*. New York: Academic Press.]

The free energy change, which we henceforth call the *group transfer potential*, is given by

$$\Delta G^\circ = -RT \ln K_{\text{eq}} \quad (3.20)$$

where K_{eq} is the equilibrium constant for the group transfer, which is normally written as

$$K_{\text{eq}} = \frac{[\text{ADP}][\text{P}_i]}{[\text{ATP}][\text{H}_2\text{O}]} \quad (3.21)$$

Even this set of equations represents a simplification because ATP, ADP, and P_i all exist in solutions as a mixture of ionic species. This problem is discussed in a later section. For now, it is enough to note that the free energy changes listed in Table 3.1 are the group transfer potentials observed for transfers to water under physiological conditions at 25°C.

Similarly, in the case of an oxidation–reduction reaction

we do not really mean that A oxidizes independently. What we really mean (and what is much more likely in biochemical systems) is that the electron is transferred to a suitable acceptor:

and the relevant free energy relationship is

$$\Delta \mathcal{E}_o = \frac{-\Delta G^\circ}{n\mathcal{F}} \quad (3.22c)$$

where $\mathcal{E}_o$ is the standard reduction potential, n is the number of electron equivalents transferred, and $\mathcal{F}$ is **Faraday's constant**.

3.6 What Are Reduction Potentials, and How Are They Used to Account for Free Energy Changes in Redox Reactions?

NADH and reduced flavoproteins ($[\text{FADH}_2]$) are two reduced compounds that appear often in biological redox (electron transfer) reactions. These compounds have a strong tendency to be oxidized—that is, to transfer electrons to other species. Oxidative phosphorylation is the metabolic process by which the energy released in a series of electron-transfer reactions is captured through the phosphorylation of ADP to form ATP. Just as the group transfer potential was used in Section 3.5 to quantitate the energy of phosphoryl transfer, the **standard reduction potential**, denoted by $\mathcal{E}_o'$, quantitates the tendency of chemical species to be reduced or oxidized. The standard reduction potential difference describing electron transfer between two species,

is related to the free energy change for the process by

$$\Delta G^{\circ'} = -n\mathcal{F}\Delta \mathcal{E}_o' \quad (3.23)$$

where n represents the number of electrons transferred; $\mathcal{F}$ is Faraday's constant, 96,485 J/V · mol; and $\Delta \mathcal{E}_o'$ is the difference in reduction potentials between the donor and acceptor. This relationship is straightforward, but it depends on a standard of reference by which reduction potentials are defined.

3.6a Standard Reduction Potentials Are Measured in Reaction Half-Cells

Standard reduction potentials are determined by measuring the voltages generated in **reaction half-cells** (Figure 3.13). A half-cell consists of a solution containing 1 M concentrations of both the oxidized and reduced forms of the substance whose reduction

Figure 3.13 Experimental apparatus used to measure the standard reduction potential of the indicated redox couples: (a) the acetaldehyde/ethanol couple and (b) the fumarate/succinate couple.

potential is being measured and a simple electrode. (Together, the oxidized and reduced forms of the substance are referred to as a **redox couple**.) Such a **sample half-cell** is connected to a **reference half-cell** and electrode via a conductive bridge (usually a salt-containing agar gel). A sensitive potentiometer (voltmeter) connects the two electrodes so that the electrical potential (voltage) between them can be measured. The reference half-cell normally contains 1 *M* H^+ in equilibrium with H_2 gas at a pressure of 1 atm. The H^+/H_2 reference half-cell is arbitrarily assigned a standard reduction potential of 0.0 V. The standard reduction potentials of all other redox couples are defined relative to the H^+/H_2 reference half-cell on the basis of the sign and magnitude of the voltage (electromotive force, emf) registered on the potentiometer (Figure 3.13).

If electron flow between the electrodes is toward the sample half-cell, reduction occurs spontaneously in the sample half-cell and the reduction potential is said to be positive. If electron flow between the electrodes is away from the sample half-cell and toward the reference cell, the reduction potential is said to be negative because electron loss (oxidation) is occurring in the sample half-cell. Strictly speaking, the standard reduction potential, $\mathcal{E}_o'$, is the electromotive force generated at 25°C and pH 7.0 by a sample half-cell (containing 1 *M* concentrations of the oxidized and reduced species) with respect to a reference half-cell. (Note that the reduction potential of the hydrogen half-cell is pH dependent. The standard reduction potential, 0.0 V, assumes 1 *M* H^+ . The hydrogen half-cell measured at pH 7.0 has an $\mathcal{E}_o'$ of -0.421 V.)

How Standard Reduction Potentials Are Determined: Two Examples Figure 3.13a shows a sample/reference half-cell pair for measurement of the standard reduction potential of the acetaldehyde/ethanol couple. Because electrons flow toward the reference half-cell and away from the sample half-cell, the standard reduction potential is negative, specifically -0.197 V. In contrast, the fumarate/succinate couple (Figure 3.13b) causes electrons to flow from the reference half-cell to the sample half-cell; that is, reduction occurs, and the reduction potential is thus positive. For each half-cell, a **half-cell reaction** describes the reaction taking place. For the fumarate/succinate half-cell coupled to a H^+/H_2 reference half-cell, the reaction occurring is indeed a reduction of fumarate:

However, the reaction occurring in the acetaldehyde/ethanol half-cell is the oxidation of ethanol:

3.6b $\mathcal{E}_o'$ Values Can Be Used to Predict the Direction of Redox Reactions

Some typical half-cell reactions and their respective standard reduction potentials are listed in Table 3.3. Whenever reactions of this type are tabulated, they are uniformly written as reduction reactions, regardless of what occurs in the given half-cell. The sign of the standard reduction potential indicates which reaction really occurs when the given half-cell is combined with the reference hydrogen half-cell (see Figure 3.13). Redox couples that have large positive reduction potentials have a strong tendency to accept electrons, and the oxidized form of such a couple (O_2 , for example) is a strong oxidizing agent. Redox couples with large negative reduction potentials have a strong tendency to undergo oxidation (that is, donate electrons), and the reduced form of such a couple (NADPH, for example) is a strong reducing agent.

3.6c $\mathcal{E}_o'$ Values Can Be Used to Analyze Energy Changes in Redox Reactions

The half-reactions and reduction potentials in Table 3.3 can be used to analyze energy changes in redox reactions. The oxidation of NADH to NAD^+ can be coupled with the reduction of α -ketoglutarate to isocitrate:

Table 3.3 Standard Reduction Potentials for Several Biological Reduction Half-Reactions

Reduction Half-Reaction	$\mathcal{E}'_o$ (V)
$\frac{1}{2} \text{O}_2 + 2 \text{H}^+ + 2 e^- \longrightarrow \text{H}_2\text{O}$	0.816
$\text{Fe}^{3+} + e^- \longrightarrow \text{Fe}^{2+}$	0.771
Photosystem P700	0.430

$2 \text{H}^+ + 2 e^- \longrightarrow \text{H}_2$	−0.421
Ferredoxin (spinach) (Fe^{3+}) + $e^- \longrightarrow$ ferredoxin (spinach) (Fe^{2+})	−0.430
Succinate + $\text{CO}_2 + 2 \text{H}^+ + 2 e^- \longrightarrow \alpha$ -ketoglutarate + H_2O	−0.670

*Typical values for reduction of bound FAD in flavoproteins such as succinate dehydrogenase (see Bonomi, F., Pagani, S., Cerletti, P., and Giori, C., 1983. Modification of the thermodynamic properties of the electron-transferring groups in mitochondrial succinate dehydrogenase upon binding of succinate. *European Journal of Biochemistry* 134:439–445).

This is the isocitrate dehydrogenase reaction of the citric acid cycle. Writing the two half-cell reactions, we have

In a spontaneous reaction, electrons are donated by (flow away from) the half-reaction with the more negative reduction potential and are accepted by (flow toward) the half-reaction with the more positive reduction potential. In this example, isocitrate donates electrons and NAD^+ accepts electrons. The convention defines $\Delta\mathcal{E}'_o$ as

$$\Delta\mathcal{E}'_o = \mathcal{E}'_o (\text{acceptor}) - \mathcal{E}'_o (\text{donor}) \quad (3.29)$$

Since isocitrate is the donor and NAD^+ the acceptor, so we write

$$\Delta \mathcal{E}_o' = -0.32 \text{ V} - (-0.38 \text{ V}) = +0.06 \text{ V} \quad (3.30)$$

From Equation 3.23, we can now calculate $\Delta G^{\circ'}$ as

$$\Delta G^{\circ'} = -(2)(96.485 \text{ kJ/V} \cdot \text{mol})(0.06 \text{ V}) \quad (3.31)$$

$$\Delta G^{\circ'} = -11.58 \text{ kJ/mol}$$

Note that a reaction with a net positive $\Delta \mathcal{E}_o'$ yields a negative $\Delta G^{\circ'}$, indicating a spontaneous reaction.

3.6d The Reduction Potential Depends on Concentration

We have already noted that the standard free energy change for a reaction, $\Delta G^{\circ'}$, does not reflect the actual conditions in a living cell, where reactants and products are not at standard-state concentrations (1 *M*). Equation 3.8 was introduced to permit calculations of actual free energy changes under non-standard-state conditions. Similarly, standard reduction potentials for redox couples must be modified to account for the actual concentrations of the oxidized (ox) and reduced (red) species. For any redox couple,

the actual reduction potential is given by

$$\mathcal{E} = \mathcal{E}_o' + (RT/n\mathcal{F}) \ln \left(\frac{[\text{ox}]}{[\text{red}]} \right) \quad (3.33)$$

Reduction potentials can also be quite sensitive to the molecular environment. The influence of environment is especially important for flavins, such as FAD/FADH₂ and FMN/FMNH₂. When these species are bound to their respective flavoproteins, their reduction potentials can be very different. As an example, see the standard reduction potentials shown for FAD and lipoyl dehydrogenase in Table 3.3.

3.7 Why Are Coupled Processes Important to Living Things?

Many of the reactions necessary to keep cells and organisms alive must run against their **thermodynamic potential**, that is, in the direction of positive ΔG . Among these are the synthesis of ATP and other high-energy molecules as well as the creation of ion gradients in all mammalian cells. These processes are driven in the thermodynamically unfavorable direction via *coupling* with highly favorable processes. Many such *coupled processes* are discussed later in this text. They are crucially important in intermediary metabolism, oxidative phosphorylation, and membrane transport.

We can predict whether pairs of coupled reactions will proceed spontaneously by simply summing the free energy changes for each reaction. For example, consider the reaction from glycolysis (discussed in Chapter 18) involving the conversion of phosphoenolpyruvate (PEP) to pyruvate (Figure 3.14). The hydrolysis of PEP is energetically very favorable, and it is used to drive phosphorylation of adenosine diphosphate (ADP) to form ATP, a process that is energetically unfavorable. Using values of ΔG that would be typical for a human erythrocyte:

The net reaction catalyzed by this enzyme depends upon coupling between the two reactions shown in Equations 3.34 and 3.35 to produce the net reaction shown in Equation 3.36 with a net negative ΔG . Many other examples of coupled reactions are considered in our later discussions of intermediary metabolism. In addition, many of

Figure 3.14 The pyruvate kinase reaction.

the complex biochemical systems discussed in the later chapters of this text involve reactions and processes with positive ΔG values that are driven forward by coupling to reactions with a negative ΔG .

Example The phosphofructokinase reaction in glycolysis is:

The standard-state free energy change for this reaction is $-14,200 \text{ J/mol}$.

- a. Calculate the standard-state free energy of hydrolysis of fructose-1,6-bisphosphate to fructose-6-P.

Solution

Step 1: Realize that the phosphofructokinase reaction can be combined with the hydrolysis of ATP to obtain (by subtraction) the hydrolysis of fructose-1,6-bisphosphate:

Step 2: Add these two equations and add the values of ΔG° to obtain the answer.

- b. The human red blood cell concentrations of various metabolites are:

$$\begin{aligned} [\text{ATP}] &= 1.85 \text{ mM}, [\text{ADP}] = 0.14 \text{ mM}, [\text{fructose-6-P}] = 0.014 \text{ mM}, \\ [\text{fructose-1,6-bisphosphate}] &= 0.031 \text{ mM} \end{aligned}$$

What is the cellular free energy change for the phosphofructokinase reaction at 37°C ?

Solution

Step 1: Use Equation 3.8 and insert the concentrations of the metabolites in molar concentrations:

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[\text{F1,6-bisP}][\text{ADP}]}{[\text{F6P}][\text{ATP}]} \right)$$

Step 2: Insert the correct values and solve for the answer.

$$\begin{aligned} \Delta G &= -14.2 \text{ kJ/mol} + (8.314 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \\ &\quad \ln \left(\frac{[0.031 \times 10^{-3} \text{ M}][0.14 \times 10^{-3} \text{ M}]}{[0.014 \times 10^{-3} \text{ M}][1.85 \times 10^{-3} \text{ M}]} \right) \\ \Delta G &= -18.8 \text{ kJ/mol} \end{aligned}$$

- c. What is the equilibrium constant for the phosphofructokinase reaction?

Solution

Step 1: Write down the appropriate equation:

$$\Delta G^{\circ'} = -RT \ln K_{\text{eq}}$$

Step 2: Rearrange the equation and solve.

$$\begin{aligned} \ln K_{\text{eq}} &= \frac{14,200 \text{ J/mol}}{(8.314 \text{ J/mol} \cdot \text{K})(298 \text{ K})} = 5.73 \\ K_{\text{eq}} &= 308 \end{aligned}$$

Notice that the temperature used in this calculation is the standard-state temperature, 298 K. Unless otherwise noted, equilibrium constants are always measured at standard-state temperature.

A Deeper Look

Coupling a Reaction to ATP Hydrolysis Changes Its K_{eq} by a Factor of 10^8

Consider a process, $A \rightleftharpoons B$. It could be a biochemical reaction, or the transport of an ion against a concentration gradient, or even a mechanical process (such as muscle contraction). Assume that it is a thermodynamically unfavorable reaction. Let's say for purposes of illustration that $\Delta G^{\circ'} = +13.8$ kJ/mol. From the equation,

$$\Delta G^{\circ'} = -RT \ln K_{eq}$$

we have

$$+13,800 = -(8.31 \text{ J/K} \cdot \text{mol})(298 \text{ K}) \ln K_{eq}$$

which yields

$$\ln K_{eq} = -5.57$$

Therefore,

$$K_{eq} = 0.0038 = [B_{eq}]/[A_{eq}]$$

This reaction is clearly unfavorable (as we could have foreseen from its positive $\Delta G^{\circ'}$). At equilibrium, there is one molecule of product B for every 263 molecules of reactant A. Not much A was transformed to B.

Now suppose the reaction $A \rightleftharpoons B$ is coupled to ATP hydrolysis, as is often the case in metabolism:

The thermodynamic properties of this coupled reaction are the same as the sum of the thermodynamic properties of the partial reactions:

That is,

$$\Delta G^{\circ'}_{\text{overall}} = -16.7 \text{ kJ/mol}$$

So

$$\begin{aligned} -16,700 &= -RT \ln K_{eq} = -(8.31)(298) \ln K_{eq} \\ \ln K_{eq} &= -16,700/-2476 = 6.75 \\ K_{eq} &= 850 \end{aligned}$$

Using this equilibrium constant, let's now consider the cellular situation in which the concentrations of A and B are brought to equilibrium in the presence of typical prevailing concentrations of ATP, ADP, and P_i .*

*The concentrations of ATP, ADP, and P_i in a normal, healthy bacterial cell growing at 25°C are maintained at roughly 8 mM, 8 mM, and 1 mM, respectively. Therefore, the ratio $[\text{ADP}][\text{P}_i]/[\text{ATP}]$ is about 10^{-3} . Under these conditions, ΔG for ATP hydrolysis is approximately -47.6 kJ/mol.

$$K_{eq} = \frac{[B_{eq}][\text{ADP}][\text{P}_i]}{[A_{eq}][\text{ATP}]}$$

$$850 = \frac{[B_{eq}][8 \times 10^{-3}][10^{-3}]}{[A_{eq}][8 \times 10^{-3}]}$$

$$[B_{eq}]/[A_{eq}] = 850,000$$

Comparison of the $[B_{eq}]/[A_{eq}]$ ratio for the simple $A \rightleftharpoons B$ reaction with the coupling of this reaction to ATP hydrolysis gives

$$\frac{850,000}{0.0038} = 2.2 \times 10^8$$

The equilibrium ratio of B to A is more than 10^8 times greater when the reaction is coupled to ATP hydrolysis. A reaction that was clearly unfavorable ($K_{eq} = 0.0038$) has become emphatically spontaneous!

The involvement of ATP has raised the equilibrium ratio of B/A by more than 200-million fold. It is informative to realize that this multiplication factor does not depend on the nature of the reaction. Recall that we defined $A \rightleftharpoons B$ in the most general terms. Also, the value of this equilibrium constant ratio, some 2.2×10^8 , is not at all dependent on the particular reaction chosen or its standard free energy change, $\Delta G^{\circ'}$. You can satisfy yourself on this point by choosing some value for $\Delta G^{\circ'}$ other than $+13.8$ kJ/mol and repeating these calculations (keeping the concentrations of ATP, ADP, and P_i at 8, 8, and 1 mM, as before).

ATP
(adenosine-5'-triphosphate)

3.8 | What Is the Daily Human Requirement for ATP?

This discussion of ATP and the other important high-energy compounds in biology invites an examination of the daily metabolic consumption of ATP by humans. An approximate calculation gives a somewhat surprising and impressive result. Assume that the average adult human consumes approximately 11,700 kJ (2800 kcal, that is, 2800 Calories) per day. Assume also that the metabolic pathways leading to ATP synthesis operate at a

thermodynamic efficiency of approximately 50%. Thus, of the 11,700 kJ a person consumes as food, about 5850 kJ end up in the form of synthesized ATP. As indicated earlier, the hydrolysis of 1 mole of ATP yields approximately 50 kJ of free energy under cellular conditions. This means that the body cycles through $5850/50 = 117$ moles of ATP each day. The disodium salt of ATP has a molecular weight of 551 g/mol. Using this value in a rough calculation, an average person hydrolyzes about

$$(117 \text{ moles}) \frac{551 \text{ g}}{\text{mole}} = 64,467 \text{ g of ATP per day}$$

The average adult human, with a typical weight of 70 kg or so, thus consumes approximately 65 kg of ATP per day, an amount nearly equal to their own body weight! Fortunately, we have a highly efficient recycling system for ATP/ADP utilization. The energy released from food is stored transiently in the form of ATP. Once ATP energy is used and ADP and phosphate are released, our bodies recycle it to ATP through intermediary metabolism so that it may be reused. The typical 70 kg body contains only about 50 grams of ATP/ADP total. Therefore, each ATP molecule in our bodies must be recycled nearly 1300 times each day! Were it not for this fact, at current commercial prices for ATP of about \$60 per gram, our ATP “habit” would cost almost \$4 million per day!

Foundational Biochemistry Things You Should Know after Reading Chapter 3.

- Isolated systems exchange neither matter nor energy with their surroundings.
- Closed systems exchange energy but not matter with their surroundings.
- Open systems exchange both matter and energy with their surroundings.
- The first law of thermodynamics—the total energy of an isolated system is conserved.
- Enthalpy, H , is the heat content of a system.
- The second law of thermodynamics—systems tend toward disorder and randomness.
- Entropy, S , represents energy dispersion.
- The third law of thermodynamics—the entropy of a crystalline, perfectly ordered substance is exactly zero at 0 K.
- Free energy is the capacity to do work.
- Free energy depends on reactant and product concentrations (Equation 3.8).
- The equilibrium for a reaction in solution is a function of ΔG° (Equation 3.9).
- Free energy is pH dependent if protons are produced or consumed in a reaction.
- $\Delta G'^\circ$ symbolizes the standard-state free energy change at pH 7.
- Reduced coenzymes and high-energy phosphates mediate flow of energy from exergonic reactions to endergonic reactions.
- High-energy phosphates include phosphoric anhydrides, enol phosphates, acyl phosphates, and guanidine phosphates.
- High-energy phosphates are not long-term energy storage substances, but rather, transient forms of stored energy.
- ATP is an intermediate energy-shuttle molecule.
- The $\Delta G'^\circ$ for ATP hydrolysis used in this text is -30.5 kJ/mol.
- Phospho(enol)pyruvate (PEP) has the largest $\Delta G'^\circ$ of hydrolysis of the high-energy phosphates (-62.2 kJ/mol).
- Group transfer potentials quantify the reactivity of functional groups.
- The favorable $\Delta G'^\circ$ of hydrolysis of phosphoric anhydrides is due to electrostatic, ionization, and resonance effects.
- The $\Delta G'^\circ$ of ATP depends on pH and on the concentration of metal ions.
- The cellular ΔG of ATP hydrolysis depends on the concentrations of ATP, ADP, and P_i .
- Reactions and processes with unfavorable ΔG can be made favorable by coupling with favorable processes, such as the hydrolysis of ATP.
- Humans typically consume their own body weight in ATP each day.
- The typical human body contains about 50 grams of ATP. Recycling of each molecule approximately 1300 times per day satisfies the body's ATP needs.
- $\mathcal{E}_0'$ values can be used to predict the direction of redox reactions.
- $\mathcal{E}_0'$ values can be used to analyze energy changes in redox reactions. The reduction potential depends on concentration.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Using Thermodynamic Equations** A reaction was studied in the laboratory and the following thermodynamic data were obtained at 20°C: $\Delta H^\circ = 600 \text{ kJ/mol}$ and $\Delta S^\circ = 2000 \text{ J/mol}$. This resulted in an estimate for $\Delta G^\circ = 14 \text{ kJ/mol}$, making the reaction “non-spontaneous.” However, in cells of the human body this reaction may actually occur spontaneously, even without the help of any proteins, enzymes, or other biomolecules. Explain and show your calculations.

- Calculating K_{eq} and ΔG from Concentrations** An enzymatic hydrolysis of fructose-1-P,

was allowed to proceed to equilibrium at 25°C. The original concentration of fructose-1-P was 0.2 M, but when the system had reached equilibrium, the concentration of fructose-1-P was only $6.52 \times 10^{-5} \text{ M}$. Calculate the equilibrium constant for this reaction and the free energy of hydrolysis of fructose-1-P.

- Calculating ΔG° and ΔS° from ΔH°** The equilibrium constant for some process $\text{A} \rightleftharpoons \text{B}$ is 0.5 at 20°C and 10 at 30°C. Assuming that ΔH° is independent of temperature, calculate ΔH° for this reaction. Determine ΔG° and ΔS° at 20°C and at 30°C. Why is it important in this problem to assume that ΔH° is independent of temperature?
- Calculating ΔG from ΔG°** The standard-state free energy of hydrolysis for acetyl phosphate is $\Delta G^\circ = -42.3 \text{ kJ/mol}$.

Calculate the free energy change for acetyl phosphate hydrolysis in a solution of 2 mM acetate, 2 mM phosphate, and 3 nM acetyl phosphate.

- Understanding State Functions** Define a state function. Name three thermodynamic quantities that are state functions and three that are not.
- Thermodynamics and Spontaneous/Non-Spontaneous Processes** Passive diffusion, the movement of molecules from an area of high concentration to an area of low concentration, is an important transport mechanism in biochemistry. In almost all cases, passive diffusion is a spontaneous process. Using the thermodynamic terms discussed in this chapter, explain why this process would be spontaneous.

- Calculating the Effect of pH on ΔG°** ATP hydrolysis at pH 7.0 is accompanied by release of a hydrogen ion to the medium

If the ΔG° for this reaction is -30.5 kJ/mol , what is ΔG° (that is, the free energy change for the same reaction with all components, including H^+ , at a standard state of 1 M)?

- Calculating K_{eq} and ΔG° for Coupled Reactions** For the process $\text{A} \rightleftharpoons \text{B}$, $K_{\text{eq}}(\text{AB})$ is 0.02 at 37°C. For the process $\text{B} \rightleftharpoons \text{C}$, $K_{\text{eq}}(\text{BC})$ is 1000 at 37°C.
 - Determine $K_{\text{eq}}(\text{AC})$, the equilibrium constant for the overall process $\text{A} \rightleftharpoons \text{C}$, from $K_{\text{eq}}(\text{AB})$ and $K_{\text{eq}}(\text{BC})$.
 - Determine standard-state free energy changes for all three processes, and use $\Delta G^\circ(\text{AC})$ to determine $K_{\text{eq}}(\text{AC})$. Make sure that this value agrees with that determined in part a of this problem.
- ΔG of Combination of Reactions** An important step of the glycolysis pathway is the conversion of 1,3-bisphosphoglycerate (BPG) into 3-phosphoglycerate (3-PG) with the release of ATP: $\text{BPG} + \text{ADP} \rightleftharpoons \text{3-PG} + \text{ATP}$. This reaction typically functions close to equilibrium, with $\Delta G \approx 0 \text{ kJ/mol}$. Consider a case where a second

enzyme is present that hydrolyzes ATP into AMP and pyrophosphate (PP_i): $\text{ATP} \longrightarrow \text{AMP} + \text{PP}_i$.

- Would the presence of the second enzyme increase or decrease the value of ΔG for the conversion of BPG into 3-PG?
 - What would be the sign of ΔG , negative or positive, for the combined reaction: $\text{BPG} + \text{ADP} \longrightarrow \text{3-PG} + \text{AMP} + \text{PP}_i$? Explain.
- Understanding Resonance Structures** Draw all possible resonance structures for creatine phosphate and discuss their possible effects on resonance stabilization of the molecule.
 - Calculating K_{eq} from ΔG°** Write the equilibrium constant, K_{eq} , for the hydrolysis of creatine phosphate and calculate a value for K_{eq} at 25°C from the value of ΔG° in Table 3.2.
 - Imagining Creatine Phosphate and Glycerol-3-Phosphate as Energy Carriers** Imagine that creatine phosphate, rather than ATP, is the universal energy carrier molecule in the human body. Repeat the calculation presented in Section 3.8, calculating the weight of creatine phosphate that would need to be consumed each day by a typical adult human if creatine phosphate could not be recycled. If recycling of creatine phosphate were possible, and if the typical adult human body contained 20 grams of creatine phosphate, how many times would each creatine phosphate molecule need to be turned over or recycled each day? Repeat the calculation assuming that glycerol-3-phosphate is the universal energy carrier and that the body contains 20 grams of glycerol-3-phosphate.
 - Calculating ΔG in a Rat Liver Cell** Calculate the free energy of hydrolysis of ATP in a rat liver cell in which the ATP, ADP, and P_i concentrations are 3.4, 1.3, and 4.8 mM, respectively.
 - Calculating ΔG° and K_{eq} from Cellular Concentrations** Hexokinase catalyzes the phosphorylation of glucose from ATP, yielding glucose-6-P and ADP. The standard-state free energy change for hydrolysis of glucose-6-P is -13.9 kJ/mol . Calculate the standard-state free energy change and equilibrium constant for the hexokinase reaction.
 - Oxidation/Reduction Potential and Thermodynamics** According to the data presented in Table 3.3, oxygen has a very high reduction potential, meaning that it is a potent oxidizing agent. However, oxygen does not spontaneously oxidize nutrients. Refer to Section 3.4 and explain what impact enzymes may have.
 - Evaluating Reactivity of High-Energy Molecules** Would you expect the free energy of hydrolysis of acetoacetyl-coenzyme A (see diagram) to be greater than, equal to, or less than that of acetyl-coenzyme A? Provide a chemical rationale for your answer.

- Assessing the Reactivity of Carbamoyl Phosphate** Consider carbamoyl phosphate, a precursor in the biosynthesis of pyrimidines:

Based on the discussion of high-energy phosphates in this chapter, would you expect carbamoyl phosphate to possess a high free energy of hydrolysis? Provide a chemical rationale for your answer.

- Assessing the Effect of Temperature on Equilibrium** You are studying the various components of the venom of a poisonous lizard. One of the venom components is a protein that appears to be temperature

sensitive. When heated, it denatures and is no longer toxic. The process can be described by the following simple equation:

There is only enough protein from this venom to carry out two equilibrium measurements. At 298 K, you find that 98% of the protein is in its toxic form. However, when you raise the temperature to 320 K, you find that only 10% of the protein is in its toxic form.

- Calculate the equilibrium constants for the T to N conversion at these two temperatures.
- Use the data to determine the ΔH° , ΔS° , and ΔG° for this process.

19. Assessing the Effect of pH on Metabolic Reactions The difference between ΔG° and $\Delta G'^\circ$ was discussed in Section 3.3. Consider the hydrolysis of acetyl phosphate (Figure 3.7) and determine the value of ΔG° for this reaction at pH 2, 7, and 12. The value of $\Delta G'^\circ$ for the enolase reaction (Figure 3.8) is 1.8 kJ/mol. What is the value of ΔG° for enolase at pH 2, 7, and 12? Why is this case different from that of acetyl phosphate?

20. Analyzing the Energetics of Coupled Reactions What is the significance of the magnitude of $\Delta G'^\circ$ for ATP hydrolysis in the calculations in the Deeper Look box “ATP Changes the K_{eq} by a Factor of $10^{8''}$ ”? Repeat these calculations for the case of coupling of a reaction to 1,3-bisphosphoglycerate hydrolysis to see what effect this reaction would have on the equilibrium ratio for components A and B under the conditions stated on this page.

21. The acyl-CoA synthetase reaction is:

- $\Delta G'^\circ = -0.8$ kJ/mol. Use data from Table 3.1 to determine the standard-state free energy of hydrolysis of fatty-acyl CoA. The concentrations of various metabolites in the human red blood cell are: $[\text{CoASH}] = 0.12$ mM, $[\text{fatty acid}] = 0.001$ mM, $[\text{AMP}] = 0.14$ mM, $[\text{ATP}] = 1.85$ mM, $[\text{PP}_i] = [0.5$ mM]
 - What is the equilibrium constant for the fatty-acyl CoA synthetase reaction?
 - What is the cellular free energy change for the fatty-acyl CoA synthetase reaction at 37°C?
- 22.** The standard-state free energy change ($\Delta G'^\circ$) for hydrolysis of carbamoyl phosphate is -40.47 kJ/mol.

- What is the free energy change (ΔG) for carbamoyl phosphate hydrolysis in a solution in which the concentrations are

$[\text{carbamoyl phosphate}] = 2.5$ mM, $[\text{carbamate}] = 1.5$ mM, $[\text{P}_i] = 1$ mM?

- What is the equilibrium constant for the carbamoyl phosphate hydrolysis reaction?
 - In the carbamoyl phosphate synthetase reaction, ADP is phosphorylated by carbamoyl phosphate to form ATP:
 $\text{ADP} + \text{carbamoyl phosphate} \longrightarrow \text{ATP} + \text{carbamate}$
 What is the standard-state free energy change for this reaction?
 - What is the equilibrium constant for the carbamoyl phosphate synthetase?
- 23.** The hydrolysis of 1,3-bisphosphoglycerate is favorable, due in part to the increased resonance stabilization of the products of the reaction. Draw resonance structures for the reactant and the products of this reaction to establish that this statement is true.
- 24.** The acyl-CoA synthetase reaction activates fatty acids for oxidation in cells:
 $\text{R-COO}^- + \text{CoASH} + \text{ATP} \longrightarrow \text{R-COSCoA} + \text{AMP} + \text{pyrophosphate}$
 The reaction is driven forward in part by hydrolysis of ATP to AMP and pyrophosphate. However, pyrophosphate undergoes further cleavage to yield two phosphate anions. Discuss the energetics of this reaction both in the presence and absence of pyrophosphate cleavage.
- 25.** You have been hired to work in an independent drug- and chemical-testing lab and your first assignment involves creatine, a molecule found in skeletal muscle that reacts with ATP to produce creatine phosphate and ADP (the so-called creatine kinase reaction, which has a ΔG in skeletal muscle of 8040 J/mol). During the first few seconds of intense muscular effort, this reaction runs in reverse, producing extra ATP to support muscle contraction. For your first assignment, your supervisor asks you to determine the concentration of creatine in resting human muscle. She tells you that the muscle tissue contains 1.85 mM ATP, 0.14 mM ADP, and 25 mM creatine phosphate. Use the information provided here as well as in Table 3.1 to determine the creatine concentration in muscle.

Think-Pair-Share Question

Create An Electron Transport Pathway Consider the figure shown. Electrons need to move from NADH to O_2 through a number of intermediates. The following intermediates are available (in no particular order): UQ, Cytochrome c (Fe^{3+}), FMN, Cytochrome b_L (Fe^{3+}). Consult information given in Table 3.3.

- Assign appropriate intermediates to beakers B, C, D, and E.
- For each pair of beakers, write a balanced equation and calculate the overall reduction potential $\Delta \mathcal{E}_0'$ of the redox reactions.
- For the entire system, write a balanced equation and calculate the overall reduction potential $\Delta \mathcal{E}_0'$.

Amino Acids and the Peptide Bond

4

To hold, as 'twere, the mirror up to nature.

William Shakespeare
Hamlet

David W. Grisham

◀ All objects have mirror images. Like many molecules, amino acids exist in mirror-image forms (stereoisomers) that are not superimposable. Only the L-isomers of amino acids commonly occur in nature. (Three Sisters Wilderness, central Oregon. The Middle Sister, reflected in an alpine lake.)

Essential Question

Proteins are the indispensable agents of biological function, and **amino acids** are the building blocks of proteins. **Why are amino acids uniquely suited to their role as the building blocks of proteins?**

The stunning diversity of the thousands of proteins found in nature arises from the intrinsic properties of only 20 commonly occurring amino acids. These features include (1) the capacity to polymerize, (2) novel acid–base properties, (3) varied structure and chemical functionality in the amino acid side chains, and (4) chirality. This chapter describes each of these properties, laying a foundation for discussions of protein structure, enzyme function, and many other subjects in later chapters.

4.1 What Are the Structures and Properties of Amino Acids?

The functions of all proteins depend on the structures and properties of the twenty common amino acids. This section describes the essential features of these amino acid building blocks.

4.1a Typical Amino Acids Contain a Central Tetrahedral Carbon Atom

The structure of a single typical amino acid is shown in Figure 4.1. Central to this structure is the tetrahedral alpha (α) carbon (C_α), which is covalently linked to both the amino group and the carboxyl group. Also bonded to this α -carbon are a hydrogen and a variable side chain. It is the side chain, the so-called **R group**, that gives each amino acid its identity. The detailed acid–base properties of amino acids are discussed in the following sections. It is sufficient for now to realize that in a neutral solution

Key Questions

- 4.1 What Are the Structures and Properties of Amino Acids?
- 4.2 What Are the Acid–Base Properties of Amino Acids?
- 4.3 What Reactions Do Amino Acids Undergo?
- 4.4 What Are the Optical and Stereochemical Properties of Amino Acids?
- 4.5 What Are the Spectroscopic Properties of Amino Acids?
- 4.6 How Are Amino Acid Mixtures Separated and Analyzed?
- 4.7 What Is the Fundamental Structural Pattern in Proteins?

(pH 7), the carboxyl group exists as —COO^- and the amino group as —NH_3^+ . Because the resulting amino acid contains one positive and one negative charge, it is a neutral molecule called a **zwitterion**. Amino acids are also *chiral* molecules. With four different groups attached to it, the α -carbon is said to be *asymmetric*. The two possible configurations for the α -carbon constitute nonsuperimposable mirror-image isomers or enantiomers. Details of amino acid stereochemistry are discussed in Section 4.4.

4.1b Amino Acids Can Join via Peptide Bonds

The crucial feature of amino acids that allows them to polymerize to form peptides and proteins is the existence of their two identifying chemical groups: the amino (—NH_3^+) and carboxyl (—COO^-) groups, as shown in Figure 4.2. The amino and carboxyl groups of amino acids can react in a head-to-tail fashion, eliminating a water molecule and forming a covalent amide linkage, which, in the case of peptides and proteins, is typically referred to as a **peptide bond**. The equilibrium for this reaction in aqueous solution favors peptide bond hydrolysis. Thus, peptide bond formation requires energy input.

Repetition of the reaction shown in Figure 4.2 produces **polypeptides** and **proteins**. The remarkable properties of proteins, described throughout this text, all depend in one way or another on the unique properties and chemical diversity of the 20 common amino acids.

Careers in Chemistry

Image credit: Camila Falquez

Vanessa A. Nadal

Vanessa A. Nadal is an adjunct Professor of Law at Fordham University where she specializes in the regulation of cosmetics. Interested in life sciences at an early age, Vanessa interned at a few biology-focused laboratories before earning a B.S. in Chemical Engineering from MIT. She worked as a research and development scientist at Johnson and Johnson, developing and testing innovative technologies for skincare products, but then turned her sights to law, earning a Juris Doctorate degree from Fordham.

After several years working at legal firms and also as an extern at the Supreme Court of NY Appellate Division, she assumed her present position at Fordham, where she co-created the first course on U.S. Cosmetics Regulation. She teaches students about the governmental, industrial, and societal regulation of cosmetics, and other beauty products. Nadal's deep understanding of the chemistry and biology behind cosmetics development and use, combined with her knowledge of food and drug law, are the foundation for her work.

4.1c There Are 20 Common Amino Acids

The structures and abbreviations for the 20 amino acids commonly found in proteins are shown in Figure 4.3. All the amino acids except proline have both free α -amino and free α -carboxyl groups (Figure 4.1). There are several ways to classify the common amino acids. The most useful of these classifications is based on the polarity of the side chains. Thus, the structures shown in Figure 4.3 are grouped into the following categories: (1) nonpolar or hydrophobic amino acids, (2) neutral (uncharged) but polar amino acids, (3) acidic amino acids (which have a net negative charge at pH 7.0), and (4) basic amino acids (which have a

Figure 4.1 Anatomy of an amino acid. Except for proline and its derivatives, all of the amino acids commonly found in proteins possess this type of structure.

Figure 4.2 The α -COOH and α -NH₃⁺ groups of two amino acids can react with the resulting loss of a water molecule to form a covalent amide bond.

net positive charge at pH 7). In later chapters, the importance of this classification system for predicting protein properties becomes clear. Also shown in Figure 4.3 are the three-letter and one-letter codes used to represent the amino acids. These codes are useful when displaying and comparing the sequences of proteins in shorthand form. (Note that several of the one-letter abbreviations are phonetic in origin: arginine = “Rginine” = R, phenylalanine = “Fenylalanine” = F, aspartic acid = “asparDic” = D.)

Nonpolar Amino Acids The nonpolar amino acids (Figure 4.3a) are critically important for the processes that drive protein chains to *fold*, that is to form their natural (and functional) structures, as shown in Chapter 6. Amino acids termed *nonpolar* include all those with alkyl chain R groups (alanine, valine, leucine, and isoleucine), as well as proline (with its unusual cyclic structure); methionine (one of the two sulfur-containing amino acids); and two aromatic amino acids, phenylalanine and tryptophan. Tryptophan is sometimes considered a borderline member of this group because it can interact favorably with water via the N—H moiety of the indole ring. Proline, strictly speaking, is not an amino acid but rather an α -imino acid.

Polar, Uncharged Amino Acids All the polar, uncharged amino acids (Figure 4.3b), except for glycine, contain R groups that can (1) form hydrogen bonds with water, and (2) play a variety of nucleophilic roles in enzyme reactions. These amino acids are usually more soluble in water than the nonpolar amino acids. The amide groups of asparagine and glutamine; the hydroxyl groups of tyrosine, threonine, and serine; and the sulfhydryl group of cysteine are all good hydrogen bond-forming moieties. Glycine, the simplest amino acid, has only a single hydrogen for an R group, and this hydrogen is not a good hydrogen bond former. Glycine’s solubility properties are mainly influenced by its polar amino and carboxyl groups, and thus glycine is best considered a member of the polar, uncharged group. It should be noted that tyrosine has significant nonpolar characteristics due to its aromatic ring and could arguably be placed in the nonpolar group. However, with a pK_a of 10.1, tyrosine’s phenolic hydroxyl is a charged, polar entity at high pH.

Acidic Amino Acids There are two acidic amino acids—aspartic acid and glutamic acid—whose R groups contain a carboxyl group (Figure 4.3c). These side-chain carboxyl groups are weaker acids than the α -COOH group but are sufficiently acidic to exist as —COO^- at neutral pH. Aspartic acid and glutamic acid thus have a net negative charge at pH 7. These forms are appropriately referred to as aspartate and glutamate. These negatively charged amino acids play several important roles in proteins. Many proteins that bind metal ions for structural or functional purposes possess metal-binding sites containing one or more aspartate and glutamate side chains. The acid–base chemistry of such groups is considered in detail in Section 4.2.

(a) Nonpolar (hydrophobic)

(b) Polar, uncharged

(c) Acidic

Figure 4.3 The 20 amino acids that are building blocks of most proteins can be classified as (a) nonpolar (hydrophobic); (b) polar, neutral; (c) acidic; or (d) basic. The side chains (R groups) are highlighted in yellow. Note that all these amino acids are shown in their (lowest pH) most protonated forms, for consistency. The various protonation states are discussed in Section 4.2.

Figure 4.3 continued

Basic Amino Acids Three of the common amino acids have side chains with net positive charges at neutral pH: histidine, arginine, and lysine (Figure 4.3d). Histidine contains an imidazole group, arginine contains a guanidino group, and lysine contains a protonated alkyl amino group. The side chains of the latter two amino acids are fully protonated at pH 7, but histidine, with a side-chain pK_a of 6.0, is only 10% protonated at pH 7. With a pK_a near neutrality, histidine side chains play important roles as proton donors and acceptors in many enzyme reactions. Histidine-containing peptides are important biological buffers, as discussed in Chapter 2. Arginine and lysine side chains, which are protonated under physiological conditions, participate in electrostatic interactions in proteins.

4.1d Are There Other Ways to Classify Amino Acids?

There are alternative ways to classify the 20 common amino acids. For example, it would be reasonable to imagine that the amino acids could be described as hydrophobic, hydrophilic, or amphipathic:

Hydrophobic:		Hydrophilic:		Amphipathic:
Alanine	Proline	Arginine	Glutamine	Lysine
Glycine	Valine	Asparagine	Histidine	Methionine
Isoleucine		Aspartic acid	Serine	Tryptophan
Leucine		Cysteine	Threonine	Tyrosine
Phenylalanine		Glutamic acid		

Lysine can be considered amphipathic because its R group consists of an aliphatic side chain, which can interact with hydrophobic amino acids in proteins, and an amino group, which is normally charged at neutral pH. Methionine is the least polar of the amphipathic amino acids, but its thioether sulfur can be an effective metal ligand in proteins. Cysteine can deprotonate at pH values greater than 7, and the thiolate anion is the most potent nucleophile that can be generated among the 20 common acids. The imidazole ring of histidine has two nitrogen atoms, each with an H. The pK for dissociation of the first of these two H is around 6. However, once one N—H has dissociated, the pK value for the other becomes greater than 10.

A Deeper Look

Why Nature Chose Selenium

Small amounts of selenium—mostly as selenocysteine (Sec)—are found in all three domains of life—Eukarya, Archaea, and Bacteria. Humans have 25 genes for selenoproteins, and half of these are enzymes involved in homeostasis of oxidation–reduction processes. What chemical properties of selenium explain the role of selenocysteine in biology?

Selenium is typically a replacement for its Group 16 cousin, sulfur, and one of the most notable differences is that the pK_a of the selenocysteine-Se-H group (5.2) is much lower than that of cysteine-SH (8.3). Thus, Sec is fully deprotonated at physiological pH and Sec is an even better nucleophile than Cys. On the other hand, redox chemistry (both for one-electron and two-electron redox reactions) is the biggest difference between the two. The outer valence electrons of selenium are more loosely held than those of sulfur, and selenium cannot form π bonds of any type. As a much better nucleophile, Se will react faster than S with reactive oxygen species. And, the lack of π bond character in the Se-O bond means that the Se-oxides are much more readily reduced than comparable S-oxides. This combination of properties means that the replacement of sulfur with selenium creates molecules more resistant to oxidation.

Human selenoenzymes are involved in peroxide removal, activation and inactivation of thyroid hormones, repair of oxidized methionine residues in proteins, immune system regulation, mammalian development, and both pro- and anti-cancer activities. For example, methionine sulfoxide (see figure) accumulates in proteins and tissues with time and is thought to contribute to many aspects of aging. A selenoprotein, methionine sulfoxide reductase, reverses this process as shown.

Figure 4.4 The structures of several amino acids that are less common but nevertheless found in certain proteins. Hydroxylysine and hydroxyproline are found in connective-tissue proteins; pyroglutamic acid is found in bacteriorhodopsin (a protein in *Halobacterium halobium*).

4.1e Amino Acids 21 and 22—and More?

Although uncommon, natural amino acids beyond the well-known 20 actually do occur. Selenocysteine (Figure 4.4) was first identified in 1986 and it has since been found in a variety of organisms.

More recently, Joseph Krzycki and his colleagues at Ohio State University have discovered a lysine derivative—pyrrolysine—in several archaeal species, including *Methanosarcina barkeri*, a bottom-dwelling microbe of fresh-water lakes. **Pyrrolysine** (Figure 4.4) and selenocysteine both are incorporated naturally into proteins thanks to specific modifications that occur during the reactions of protein synthesis.

Both selenocysteine and pyrrolysine bring novel structural and chemical features to the proteins that contain them. How many more unusual amino acids might be incorporated in proteins in a similar manner?

4.1f Several Amino Acids Occur Only Rarely in Proteins

There are several amino acids that occur only rarely in proteins and are produced by modifications of one of the 20 amino acids already incorporated into a protein (Figure 4.4). These include **hydroxylysine** and **hydroxyproline**, which are found mainly in the collagen and gelatin proteins; **pyroglutamic acid**, which is found in a light-driven proton-pumping protein called bacteriorhodopsin; and **γ -carboxyglutamic acid**, which is found in calcium-binding proteins.

4.2 | What Are the Acid–Base Properties of Amino Acids?

The functions of proteins are almost always dependent on the protonation states of their ionizable side chains. This section describes the acid–base properties and behavior of the amino acids.

4.2a Amino Acids Are Weak Polyprotic Acids

From a chemical point of view, the common amino acids are all weak polyprotic acids. The ionizable groups are not strongly dissociating ones, and the degree of dissociation thus depends on the pH of the medium. All the amino acids contain at least two dissociable hydrogens.

Consider the acid–base behavior of glycine, the simplest amino acid. At low pH, both the amino and carboxyl groups are protonated and the molecule has a net positive charge. If the counterion in solution is a chloride ion, this form is referred to as **glycine hydrochloride**. If the pH is increased, the carboxyl group is the first to dissociate, yielding the neutral zwitterionic species Gly^0 (Figure 4.5). A further increase in pH eventually

Figure 4.5 The ionic forms of the amino acids that lack an ionizable sidechain. The cationic form is the low pH form, and the titration of the cationic species with base yields the zwitterion and finally the anionic form.

Critical Developments in Biochemistry

Adding New Chemistry to Proteins with Unnatural Amino Acids

The astounding diversity of protein structure and function in the biosphere derives almost entirely from the 20 common amino acids. Nonetheless, it is intriguing to imagine how protein function can be changed by creating and introducing new ‘unnatural’ amino acids. Peter Schultz and his coworkers at the Scripps Research Institute have developed powerful methodologies that facilitate the incorporation of more than 160 novel and unnatural amino acids (UAAs) into proteins in *Escherichia coli*, yeast, and mammalian cells. Incorporation of these UAAs (two are shown here) at unique sites in proteins enables an array of new methods for the study of structure and function in these proteins, including the introduction of new catalytic functionality. For example, aniline is known to catalyze the formation of hydrazones by condensation of carbonyl compounds with hydrazines (figure, part a). Insertion of *p*-aminophenylalanine (pAF), an amino acid analogue of aniline, into LmrR, a bacterial protein with no catalytic function, creates a **designer enzyme** that carries out the same type of reaction. Similarly, 8-hydroxyquinoline (figure, part b) is known to bind tightly to a variety of metals, including Cu^{2+} , Zn^{2+} , and Rh^{3+} . Incorporation of an amino acid analogue of 8-hydroxyquinoline (HQ-Ala) into the same noncatalytic LmrR protein produces instead a *metalloenzyme* that binds Cu^{2+} tightly and carries out the double-bond hydration reaction shown, and other Cu^{2+} -dependent reactions. UAA methodology is enabling the creation of many new designer enzymes. It also has therapeutic potential for the development of novel antibodies, immunotoxins, and vaccines as well as new medical imaging probes.

The chemistry of some unnatural amino acids. (a) Structures of aniline and *p*-aminophenylalanine (pAF), and the reaction between 4-nitrobenzaldehyde (4-NBA) and 4-hydrazino-7-nitro-2,1,3-benzoxadiazole to form the corresponding hydrazone. (b) Structures of 8-hydroxyquinoline and 2-amino-3-(8-hydroxyquinolin-3-yl)propanoic acid (HQ-Ala), and the reaction of an α,β -unsaturated 2-acyl pyridine to form the corresponding β -hydroxy ketone product.

Table 4.1 pK_a Values of Common Amino Acids

Amino Acid	α -COOH pK_a	α -NH ₃ ⁺ pK_a	R group pK_a
Alanine	2.4	9.7	
Arginine	2.2	9.0	12.5
Asparagine	2.0	8.8	
Aspartic acid	2.1	9.8	3.9
Cysteine	1.7	10.8	8.3
Glutamic acid	2.2	9.7	4.3
Glutamine	2.2	9.1	
Glycine	2.3	9.6	
Histidine	1.8	9.2	6.0
Isoleucine	2.4	9.7	
Leucine	2.4	9.6	
Lysine	2.2	9.0	10.5
Methionine	2.3	9.2	
Phenylalanine	1.8	9.1	
Proline	2.1	10.6	
Serine	2.2	9.2	~13
Threonine	2.6	10.4	~13
Tryptophan	2.4	9.4	
Tyrosine	2.2	9.1	10.1
Valine	2.3	9.6	

results in dissociation of the amino group to yield the negatively charged **glycinate**. If we denote these three forms as Gly⁺, Gly⁰, and Gly[−], we can write the first dissociation of Gly⁺ as

and the dissociation constant K_1 as

$$K_1 = \frac{[\text{Gly}^0][\text{H}_3\text{O}^+]}{[\text{Gly}^+]}$$

Values for K_1 for the common amino acids are typically 0.4 to $1.0 \times 10^{-2} M$, so that typical values of pK_1 are in the range of 2.0 to 2.4 (Table 4.1). In a similar manner, we can write the second dissociation reaction as

and the dissociation constant K_2 as

$$K_2 = \frac{[\text{Gly}^-][\text{H}_3\text{O}^+]}{[\text{Gly}^0]}$$

Typical values for pK_2 are in the range of 9.0 to 9.8 . At physiological pH, the α -carboxyl group of a simple amino acid (with no ionizable side chains) is completely dissociated, whereas the α -amino group has not really begun its dissociation. The titration curve for such an amino acid is shown in Figure 4.6. Note that the isoelectric point, pI, the pH where glycine has a net charge of 0, can be calculated as $(pK_1 + pK_2)/2$.

Note that the dissociation constants of both the α -carboxyl and α -amino groups are affected by the presence of the other group. The adjacent α -amino group makes the α -COOH group more acidic (that is, it lowers the pK_a), so it gives up a proton more

Figure 4.6 Titration of glycine, a simple amino acid.

Example What is the pH of a glycine solution in which the $\alpha\text{-NH}_3^+$ group is one-third dissociated?

Answer

Step 1: Use the appropriate Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK}_a + \log_{10} \frac{[\text{Gly}^-]}{[\text{Gly}^0]}$$

Step 2: What is the pK_a for the $\alpha\text{-NH}_3^+$ group? 9.6 (Table 4.1)

Step 3: If the α -amino group is one-third dissociated, there is one part Gly^- for every two parts Gly^0 .

Step 4: Inserting these values into the Henderson-Hasselbalch equation yields

$$\begin{aligned} \text{pH} &= 9.6 + \log_{10} \frac{[1]}{[2]} \\ \text{pH} &= 9.3 \end{aligned}$$

readily than simple alkyl carboxylic acids. Thus, the pK_1 of 2.0 to 2.1 for α -carboxyl groups of amino acids is substantially lower than that of acetic acid ($\text{pK}_a = 4.76$), for example. What is the chemical basis for the low pK_a of the $\alpha\text{-COOH}$ group of amino acids? The $\alpha\text{-NH}_3^+$ (ammonium) group is strongly electron withdrawing, and the positive charge of the amino group exerts a strong field effect and stabilizes the carboxylate anion. (The effect of the $\alpha\text{-COO}^-$ group on the pK_a of the $\alpha\text{-NH}_3^+$ group is the basis for Problem 6 at the end of this chapter.)

4.2b Side Chains of Amino Acids Undergo Characteristic Ionizations

The side chains (R groups) of amino acids give them their unique character and functions. The side chains of several of the amino acids also contain dissociable groups. For example, aspartic and glutamic acids contain an additional carboxyl group, and

Figure 4.7 Titrations of glutamic acid and lysine.

lysine possesses an aliphatic amino group. Histidine contains an ionizable imidazolium proton, and arginine carries a guanidinium group. Typical pK_a values of these groups are shown in Table 4.1. The β -carboxyl group of aspartic acid and the γ -carboxyl side chain of glutamic acid exhibit pK_a values intermediate to the α -COOH on one hand and typical aliphatic carboxyl groups on the other hand. In a similar fashion, the ϵ -amino group of lysine exhibits a pK_a that is higher than that of the α -amino group but similar to that for a typical aliphatic amino group. These intermediate side-chain pK_a values reflect the slightly diminished effect of the α -carbon dissociable groups that lie several carbons removed from the side-chain functional groups. Figure 4.7 shows typical titration curves for glutamic acid and lysine, along with the ionic species that predominate at various points in the titration. The only other side-chain groups that exhibit any significant degree of dissociation are the *para*-OH group of tyrosine and the —SH group of cysteine. The pK_a of the cysteine sulfhydryl is 8.32, so it is about 5% dissociated at pH 7. The tyrosine *para*-OH group is a very weakly acidic group, with a pK_a of about 10.1. This group is essentially fully protonated and uncharged at pH 7.

It is important to note that side-chain pK_a values for amino acids in proteins can be different from the values shown in Table 4.1. On *average*, values for side chains in proteins are one pH unit closer to neutrality compared with the free amino acid values. Moreover, the local chemical environment of an amino acid in a protein can change its pK_a dramatically. For example, Lys residues in staphylococcal nuclease variants have been found to have pK_a values as low as 5.3, whereas a mutant thioredoxin possesses an Asp residue with a pK_a of 9.4.

Example

Calculating the pH of amino acid solutions:

- What is the pH of a 0.3 M solution of leucine hydrochloride?
- What is the pH of a 0.3 M sodium leucinate solution?
- What is the pH of isoelectric leucine?

Solution

Part a: Note that “hydrochloride” means that the leucine has been titrated to its fully protonated form, which will be called H_2A^+ .

Step 1: Begin by deriving the K_a from the $\text{p}K_a$ given in Table 4.1.

$$K_a = 10^{-\text{p}K_a} = 10^{-2.4} = 3.98 \times 10^{-3}$$

Step 2: Write the K_a expression:

$$K_a = \frac{[\text{H}^+][\text{HA}^0]}{[\text{H}_2\text{A}^+]} = 3.98 \times 10^{-3}$$

Step 3: Assume that only a small amount of H_2A^+ dissociates:

$$K_a = \frac{[\text{H}^+][\text{HA}^0]}{[\text{H}_2\text{A}^+]} = \frac{x^2}{0.3 - x} = 3.98 \times 10^{-3}$$

Step 4: Assume x is small compared to 0.3 M and solve for x :

$$\begin{aligned} x^2 &= (0.3)(3.98 \times 10^{-3}) = 1.19 \times 10^{-3} \\ x &= 3.45 \times 10^{-2} \\ \text{pH} &= -\log_{10}(3.45 \times 10^{-2}) = 1.46 \end{aligned}$$

Part b: Note that “sodium leucinate” means that the leucine has been titrated to the fully deprotonated form, which will be called A^- .

Step 1: The reaction for the formation of A^- is:

Step 2: Important—a K_a expression cannot be used for the fully deprotonated form because the concentration of HA^0 (the denominator in a K_a expression) goes to zero when this reaction goes to completion. So a K_b expression, based on this equation, must be used:

Step 3: Write the K_b expression:

$$K_b = \frac{[\text{HA}^0][\text{OH}^-]}{[\text{A}^-]}$$

Step 4: Derive the K_b from the $\text{p}K_a$ for the second dissociation of leucine from Table 4.1:

$$\text{p}K_a = 9.6, \text{ so } \text{p}K_b = 14 - 9.6 = 4.4$$

$$\text{Then } K_b = 10^{-4.4} = 3.98 \times 10^{-5}$$

Step 5: Write the K_b expression:

$$K_b = \frac{[\text{HA}^0][\text{OH}^-]}{[\text{A}^-]} = 3.98 \times 10^{-5}$$

Now assume that only a small amount of A^- protonates:

$$K_b = \frac{[\text{HA}^0][\text{OH}^-]}{[\text{A}^-]} = \frac{x^2}{0.3 - x} = 3.98 \times 10^{-5}$$

Step 6: Assume x is small compared to 0.3 M and solve for x :

$$\begin{aligned}x^2 &= (0.3)(3.98 \times 10^{-5}) = 1.19 \times 10^{-5} \\x &= 3.46 \times 10^{-3} = [\text{OH}^-] \\ \text{pOH} &= 2.46\end{aligned}$$

$$\text{Then pH} = 14 - \text{pOH} = 14 - 2.46 = 11.54$$

Part c: Note that the isoelectric point is the point where leucine has a net zero charge. That form, HA° , predominates at the first equivalence point in the leucine titration.

The isoelectric pH is calculated by determining the average of the two adjacent pK_a values.

$$\text{pH} = \frac{2.4 + 9.6}{2} = 6.0$$

4.3 | What Reactions Do Amino Acids Undergo?

The α -carboxyl and α -amino groups of all amino acids exhibit similar chemical reactivity. The side chains, however, exhibit specific chemical reactivities, depending on the nature of the functional groups. Whereas all of these reactivities are important in the study and analysis of isolated amino acids, it is the characteristic behavior of the side chain that governs the reactivity of amino acids incorporated into proteins. There are three reasons to consider these reactivities. Proteins can be modified in very specific ways by taking advantage of the chemical reactivity of certain amino acid side chains. The detection and quantitation of amino acids and proteins often depend on reactions that are specific to one or more amino acids and that result in color, radioactivity, or some other quantity that can be easily measured. Finally and most importantly, the biological functions of proteins depend on the behavior and reactivity of specific R groups.

A number of reactions of amino acids are noteworthy because they are essential to the degradation, sequencing, and chemical synthesis of peptides and proteins. One of these, the reaction with phenylisothiocyanate, or **Edman reagent**, involves nucleophilic attack by the amino acid α -amino nitrogen, followed by cyclization, to yield a phenylthiohydantoin (PTH) derivative of the amino acid (Figure 4.8a). PTH-amino acids can be easily identified and quantified, as shown in Section 4.6. An important amino acid side-chain reaction is formation of disulfide bonds via reaction between two cysteines. In proteins, cysteine residues form disulfide linkages that stabilize protein structure (Figure 4.8b). Related reactions are discussed in Chapter 5.

4.4 | What Are the Optical and Stereochemical Properties of Amino Acids?

The structures of proteins are influenced strongly by the asymmetric nature or ‘handedness’ of their amino acid components. This section describes the essential features and consequences of this aspect of their chemistry.

4.4a Amino Acids Are Chiral Molecules

Except for glycine, all of the amino acids isolated from proteins have four different groups attached to the α -carbon atom. In such a case, the α -carbon is said to be **asymmetric** or **chiral** (from the Greek *cheir*, meaning “hand”), and the two possible configurations for the α -carbon constitute nonsuperimposable mirror-image isomers, or **enantiomers** (Figure 4.9). Enantiomeric molecules display a special property called **optical activity**—the ability to rotate the plane of polarization of plane-polarized light. Clockwise rotation of incident light is referred to as **dextrorotatory** behavior, and counterclockwise rotation is called **levorotatory** behavior. The magnitude and direction of the optical rotation depend on the nature of the amino acid side chain

Figure 4.9 Enantiomeric molecules based on a chiral carbon atom. Enantiomers are nonsuperimposable mirror images of each other.

and can be used to reveal certain details of molecular structure. Some protein-derived amino acids at a given pH are dextrorotatory and others are levorotatory, even though all of them are of the L-configuration. The direction of optical rotation can be specified in the name by using a (+) for dextrorotatory compounds and a (−) for levorotatory compounds, as in L(+)-leucine.

4.4b Chiral Molecules Are Described by the D,L and (R,S) Naming Conventions

Two systems are commonly used to name and describe chiral molecules—the so-called D,L system and the (R,S) system.

In the **D,L system** of nomenclature, the (+) and (−) isomers of glyceraldehyde are denoted as **D-glyceraldehyde** and **L-glyceraldehyde**, respectively (see Critical Developments in Biochemistry box “Rules for Description of Chiral Centers in the (R,S) System” in this section). Absolute configurations of all other carbon-based molecules are referenced to D- and L-glyceraldehyde. When sufficient care is taken to avoid racemization of the amino acids during hydrolysis of proteins, it is found that all of the amino acids derived from natural proteins are of the L-configuration. Amino acids of the D-configuration are nonetheless found in nature, especially as components of certain peptide antibiotics, such as valinomycin, gramicidin, and actinomycin D, and in the cell walls of certain microorganisms.

Although the D,L system is commonly used, it can be ambiguous for molecules with two or more chiral centers. To address such problems, the **(R,S) system** of nomenclature for chiral molecules was proposed in 1956 by Robert Cahn, Sir Christopher Ingold, and Vladimir Prelog. In this more versatile system, priorities are assigned to each of the groups attached to a chiral center on the basis of atomic number; atoms with higher atomic numbers have higher priorities. The newer (R,S) system of nomenclature is

4.5a Phenylalanine, Tyrosine, and Tryptophan Absorb Ultraviolet Light

Many details of the structure and chemistry of the amino acids have been elucidated, or at least confirmed, by spectroscopic measurements. None of the amino acids absorb light in the visible region of the electromagnetic spectrum. Several of the amino acids, however, do absorb **ultraviolet** radiation, and all absorb in the **infrared** region. Only the aromatic amino acids phenylalanine, tyrosine, and tryptophan exhibit significant ultraviolet absorption above 250 nm, as shown in Figure 4.10. These strong absorptions can be used for spectroscopic determinations of protein concentration. The aromatic amino acids also exhibit relatively weak fluorescence, and it has recently been shown that tryptophan can exhibit *phosphorescence*—a relatively long-lived emission of light. These fluorescence and phosphorescence properties are especially useful in the study of protein structure and dynamics.

4.5b Amino Acids Can Be Characterized by Nuclear Magnetic Resonance

The development in the 1950s of **nuclear magnetic resonance** (NMR), a spectroscopic technique that involves the absorption of radio-frequency energy by certain nuclei in the presence of a magnetic field, played an important part in the chemical characterization of amino acids and proteins. Several important principles emerged from these studies. First, the **chemical shift**¹ of amino acid protons depends on their particular chemical environment and thus on the state of ionization of the amino acid. Second, the change in electron density during a titration is transmitted throughout the carbon chain in the aliphatic amino acids and the aliphatic portions of aromatic amino acids, as evidenced by changes in the chemical shifts of relevant protons. Finally, the magnitude of the **coupling constants** between protons on adjacent carbons depends in some cases on the ionization state of the amino acid. This apparently reflects differences in the preferred conformations in different ionization states. Proton NMR spectra of two amino acids are shown in Figure 4.11. Because they are highly sensitive to their environment, the chemical shifts of individual NMR signals can detect the pH-dependent

Figure 4.10 The ultraviolet absorption spectra of the aromatic amino acids at pH 6. (Source: Wetlauffer, D. B., 1962. Ultraviolet spectra of proteins and amino acids. *Advances in Protein Chemistry* 17:303–390.)

¹The chemical shift for any NMR signal is the difference in resonant frequency between the observed signal and a suitable reference signal. If two nuclei are magnetically coupled, the NMR signals of these nuclei split, and the separation between such split signals, known as the coupling constant, is likewise dependent on the structural relationship between the two nuclei.

Figure 4.11 Proton NMR spectra of several amino acids. Zero on the chemical shift scale is defined by the resonance of tetramethylsilane (TMS). (The large resonance at approximately 5 ppm is due to the normal HDO impurity in the D₂O solvent.) (Adapted from Aldrich Library of NMR Spectra.)

Critical Developments in Biochemistry

Rules for Description of Chiral Centers in the (*R,S*) System

Naming a chiral center in the (*R,S*) system is accomplished by viewing the molecule from the chiral center to the atom with the lowest priority. If the other three atoms facing the viewer then decrease in priority in a clockwise direction, the center is said to have the (*R*) configuration (where *R* is from the Latin *rectus*, meaning “right”). If the three atoms in question decrease in priority in a counterclockwise fashion, the chiral center is of the (*S*) configuration (where *S* is from the Latin *sinistrus*, meaning “left”). If two of the atoms coordinated to a chiral center are identical, the atoms bound to these

two are considered for priorities. For such purposes, the priorities of certain functional groups found in amino acids and related molecules are in the following order:

From this, it is clear that D-glyceraldehyde is (*R*)-glyceraldehyde and L-alanine is (*S*)-alanine (see figure). Interestingly, the α -carbon configuration of all the L-amino acids *except for cysteine* is (*S*). Cysteine, by virtue of its thiol group, is, in fact, (*R*)-cysteine.

The assignment of (*R*) and (*S*) notation for glyceraldehyde and L-alanine.

ionizations of amino acids and other aspects of their molecular environment. More sophisticated NMR measurements at very high magnetic fields are also used to determine the three-dimensional structures of peptides and proteins. Kurt Wüthrich received the 2002 Nobel Prize in Chemistry for developing NMR methods for determining protein structure.

4.6 How Are Amino Acid Mixtures Separated and Analyzed?

The characterization of newly discovered proteins depends on analyses that reveal their amino acid compositions. Biochemists employ a wide variety of techniques to elucidate such information.

4.6a Amino Acids Can Be Separated by Chromatography

A wide variety of methods is available for the separation and analysis of amino acids (and other biological molecules and macromolecules). All of these methods take advantage of the relative differences in the physical and chemical characteristics of amino acids, particularly ionization behavior and solubility characteristics. Separations of amino acids are usually based on **partition** properties (the tendency to associate with one solvent or phase over another) and separations based on **electrical charge**. In all of the partition methods discussed here, the molecules of interest are allowed (or forced) to flow through a medium consisting of two phases—solid–liquid, liquid–liquid, or gas–liquid. The molecules partition, or distribute themselves, between the two phases in a manner based on their particular properties and their consequent preference for associating with one or the other phase.

In 1903, a separation technique based on repeated partitioning between phases was developed by Mikhail Tsvet for the separation of plant pigments (carotenes and chlorophylls). Due to the colorful nature of the pigments thus separated, Tsvet called his technique **chromatography**. This term is now applied to a wide variety of separation methods. The success of many chromatography techniques depends on the different affinities of molecules in a mixture for two different phases—for example, solid and liquid, or liquid and gas—a phenomenon termed “partitioning.” The more frequently this partitioning can be made to occur within a given time span or over a given volume, the more efficient is the resulting separation. Chromatographic methods have advanced rapidly in recent years, due in part to the development of sophisticated new solid-phase materials. Methods important for amino acid separations include ion-exchange chromatography, gas chromatography (GC), and high-performance liquid chromatography (HPLC).

A typical HPLC chromatogram using precolumn modification of amino acids to form phenylthiohydantoin (PTH) derivatives is shown in Figure 4.12. HPLC is the chromatographic technique of choice for most modern biochemists. The very high resolution, excellent sensitivity, and high speed of this technique usually outweigh the disadvantage of relatively low capacity.

4.7 What Is the Fundamental Structural Pattern in Proteins?

Proteins play an essential role in nearly all aspects of cell structure and function. Chemically, proteins are unbranched polymers of amino acids linked head to tail, from carboxyl group to amino group, through the formation of covalent peptide bonds, a type of amide linkage (Figure 4.13).

Peptide bond formation results in the release of H_2O . The peptide “backbone” of a protein consists of the repeated sequence $\text{—N—C}_\alpha\text{—C}_o\text{—}$, where the N represents the

Figure 4.12 Gradient separation of common PTH-amino acids, which absorb UV light. Absorbance was monitored at 269 nm. PTH peaks are identified by single-letter notation for amino acid residues and by other abbreviations. D, Asp; CMC, carboxymethyl Cys; E, Glu; N, Asn; S, Ser; Q, Gln; H, His; T, Thr; G, Gly; R, Arg; MO₂, Met sulfoxide; A, Ala; Y, Tyr; M, Met; V, Val; P, Pro; W, Trp; K, Lys; F, Phe; I, Ile; L, Leu. See Figure 4.8a for PTH derivatization. (Adapted from Persson, B., and Eaker, D., 1990. An optimized procedure for the separation of amino acid phenylthiohydantoin by reversed phase HPLC. *Journal of Biochemical and Biophysical Methods* **21**:341–350.)

Figure 4.13 Peptide formation is the creation of an amide bond between the carboxyl group of one amino acid and the amino group of another amino acid.

amide nitrogen, the C_α is the α-carbon atom of an amino acid in the polymer chain, and the final C_o is the carbonyl carbon of the amino acid, which in turn is linked to the amide N of the next amino acid down the line. The geometry of the peptide backbone is shown in Figure 4.14. Note that the carbonyl oxygen and the amide hydrogen are *trans* to each other in this figure. This conformation is favored energetically because it results in less steric hindrance between nonbonded atoms in neighboring amino acids. Because the α-carbon atom of the amino acid is a chiral center (in all amino acids except glycine), the polypeptide chain is inherently asymmetric.

4.7a The Peptide Bond Has Partial Double-Bond Character

The peptide linkage is usually portrayed by a single bond between the carbonyl carbon and the amide nitrogen (Figure 4.15a). Therefore, in principle, rotation may occur about any covalent bond in the polypeptide backbone because all three kinds of bonds (N—C_α, C_α—C_o, and the C_o—N peptide bond) are single bonds. In this

Figure 4.14 The peptide bond is shown in its usual *trans* conformation of carbonyl O and amide H. The C_{α} atoms are the α -carbons of two adjacent amino acids joined in peptide linkage. The dimensions and angles are the average values observed by crystallographic analysis of amino acids and small peptides. The peptide bond is the light-colored bond between C and N. (Adapted from Ramachandran, G. N., et al., 1974. The mean geometry of the peptide unit from crystal structure data. *Biochimica et Biophysica Acta* **359**:298–302.)

Figure 4.15 The partial double-bond character of the peptide bond. Resonance interactions among the carbon, oxygen, and nitrogen atoms of the peptide group can be represented by two resonance extremes (a and b). (a) Left - The way the peptide atoms are normally drawn. (b) In an equally feasible form, the peptide bond is now a double bond; the amide N bears a positive charge and the carbonyl O has a negative charge. (c) The actual peptide bond is best described as a resonance hybrid of the forms in (a) and (b). Significantly, all of the atoms associated with the peptide group are coplanar, rotation about C_{α} —N is restricted, and the peptide is distinctly polar.

representation, the C_o and N atoms of the peptide group are both in planar sp^2 hybridization and the C_o and O atoms are linked by a π bond, leaving the nitrogen with a lone pair of electrons in a $2p$ orbital. However, another resonance form for the peptide bond is feasible in which the C_o and N atoms participate in a π bond, leaving a lone e^- pair on the oxygen (Figure 4.15b). This structure prevents free rotation about the C_o —N peptide bond because it becomes a double bond. The real nature of the peptide bond lies somewhere between these extremes; that is, it has partial double-bond character, as represented by the intermediate form shown in Figure 4.15c.

Peptide bond resonance has several important consequences. First, it restricts free rotation around the peptide bond and leaves the peptide backbone with only two rotational degrees of freedom per amino acid group: rotation around the N — C_α bond and rotation around the C_α — C_o bond. Second, the six atoms composing the peptide bond group tend to be coplanar, forming the so-called **amide plane** of the polypeptide backbone (Figure 4.16). Third, the C_o —N bond length is 0.133 nm, which is shorter than normal C—N bond lengths (for example, the C_α —N bond of 0.145 nm) but longer than typical C=N bonds (0.125 nm). Based on this measurement, the peptide bond is estimated to have 40% double-bond character. The barrier to C—N bond rotation of about 88 kJ/mol is enough to keep the amide group planar.

4.7b The Polypeptide Backbone Is Relatively Polar

Peptide bond resonance also causes the peptide backbone to be relatively polar. As shown in Figure 4.15b, the amide nitrogen is in a protonated or positively charged form, and the carbonyl oxygen is a negatively charged atom in this double-bonded resonance state. In actuality, the hybrid state of the partially double-bonded peptide arrangement gives a net positive charge of 0.28 on the amide N and an equivalent net negative charge of 0.28 on the carbonyl O. The presence of these partial charges means that the peptide bond has a permanent dipole. Nevertheless, the peptide backbone is relatively unreactive chemically, and protons are gained or lost by the peptide groups only at extreme pH conditions.

4.7c Peptides Can Be Classified According to How Many Amino Acids They Contain

Peptides are short polymers of amino acids. They are classified according to the number of amino acid units in the chain. Each unit is called an **amino acid residue**. The term describes what is left after the release of H_2O when an amino acid forms a

Figure 4.16 The coplanar relationship of the atoms in the amide group is highlighted as an imaginary shaded plane lying between two successive α -carbon atoms in the peptide backbone.

peptide link upon joining the peptide chain. **Dipeptides** have two amino acid residues, tripeptides have three, tetrapeptides four, and so on. After about 12 residues, this terminology becomes cumbersome, so peptide chains of more than 12 and less than about 20 amino acid residues are usually referred to as **oligopeptides**. When the chain exceeds several dozen amino acids in length, the term **polypeptide** is used. The distinctions between these terms are not precise.

4.7d The Amino Acids in Polypeptides Can Be Released by Acid Hydrolysis

The peptide bonds of polypeptides and proteins can be hydrolyzed by strong acid to liberate the individual amino acids. Typically, a sample of the protein is treated with 6 *N* HCl for 24 hours at 110°C in a sealed vial. Tryptophan is destroyed by acid and must be estimated by other means (usually UV spectrophotometry; see Figure 4.10) to determine its contribution to the total amino acid composition. The OH-containing amino acids serine and threonine are slowly destroyed. In contrast, peptide bonds involving hydrophobic residues such as valine and isoleucine are only slowly hydrolyzed in acid. Another complication arises because the β - and γ - amide linkages in asparagine (Asn) and glutamine (Gln) are acid labile. The side-chain amino nitrogen is released as free ammonium, and all of the Asn and Gln residues of the protein are converted to aspartic acid (Asp) and glutamic acid (Glu), respectively. The amount of ammonium released during acid hydrolysis gives an estimate of the total number of Asn and Gln residues in the original protein, but not the amounts of either.

The complex amino acid mixture in the hydrolysate obtained after digestion of a protein in 6 *N* HCl can be separated into the component amino acids by using either ion-exchange chromatography or reversed-phase high-pressure liquid chromatography (HPLC) (see Figure 4.12 and the A Deeper Look box in Chapter 5: Techniques Used in Protein Purification). The amount of each amino acid can then be determined. Amino acid analysis provides no information on the order or sequence of amino acid residues in the polypeptide chain.

Amino acids almost never occur in equimolar ratios in proteins, indicating that proteins are not composed of repeating arrays of amino acids. There are a few exceptions to this rule. Collagen, for example, contains large proportions of glycine and proline, and much of its structure is composed of (Gly-*x*-Pro) repeating units, where *x* is any amino acid. Other proteins show unusual abundances of various amino acids. For example, histones are rich in positively charged amino acids such as arginine and lysine. Histones are a class of proteins found associated with the anionic phosphate groups of eukaryotic DNA.

4.7e Proteins Are Composed of One or More Polypeptide Chains

The term **protein** broadly defines molecules composed of one or more polypeptide chains. The terms *polypeptide* and *protein* are used interchangeably in discussing single polypeptide chains. Proteins with one polypeptide chain are **monomeric proteins**. Proteins composed of more than one polypeptide chain are **multimeric proteins**. Multimeric proteins may contain only one kind of polypeptide, in which case they are **homomultimeric**, or they may be composed of several different kinds of polypeptide chains, in which instance they are **heteromultimeric**. Greek letters and subscripts are used to denote the polypeptide composition of multimeric proteins. Thus, an α_2 -type protein is a dimer of identical polypeptide subunits, or a **homodimer**. For example, hemoglobin (Table 4.2), which consists of four polypeptides of two different kinds, is an $\alpha_2\beta_2$ heteromultimer.

Polypeptide chains of proteins typically range in length from about 100 amino acids to around 2000, the number found in each of the two polypeptide chains of myosin, the contractile protein of muscle. However, exceptions abound, including human cardiac muscle titin, which has 26,926 amino acid residues and a molecular weight of 2,993,497. The average molecular weight of polypeptide chains in eukaryotic cells is about 31,700,

Table 4.2 Size of Protein Molecules*

Protein	M _r	Number of Residues per Chain	Subunit Organization
Insulin (bovine)	5733	21 (A) 30 (B)	$\alpha\beta$
Cytochrome <i>c</i> (equine)	12,500	104	α_1
Ribonuclease A (bovine pancreas)	12,640	124	α_1
Lysozyme (egg white)	13,930	129	α_1
Myoglobin (horse)	16,980	153	α_1
Chymotrypsin (bovine pancreas)	22,600	13 (α) 132 (β) 97 (γ)	$\alpha\beta\gamma$
Hemoglobin (human)	64,500	141 (α) 146 (β)	$\alpha_2\beta_2$
Serum albumin (human)	68,500	550	α_1
Hexokinase (yeast)	96,000	200	α_4
γ -Globulin (horse)	149,900	214 (α) 446 (β)	$\alpha_2\beta_2$
Glutamate dehydrogenase (liver)	332,694	500	α_6
Myosin (rabbit)	470,000	2000 (heavy, <i>h</i>) 190 (α) 149 (α') 160 (β)	$h_2\alpha_1\alpha'_2\beta_2$
Ribulose biphosphate carboxylase (spinach)	560,000	475 (α) 123 (β)	$\alpha_8\beta_8$
Glutamine synthetase (<i>E. coli</i>)	600,000	468	α_{12}

*Illustrations of selected proteins listed in Table 4.2 are drawn to constant scale.

Adapted from Goodsell, D. S., and Olson, A. J., 1993. Soluble proteins: Size, shape and function. *Trends in Biochemical Sciences* 18:65–68.

corresponding to about 270 amino acid residues. Table 4.2 is a representative list of proteins according to size. The molecular weights (M_r) of proteins can be estimated by a number of physicochemical methods such as polyacrylamide gel electrophoresis or ultracentrifugation (see A Deeper Look box “Techniques Used in Protein Purification” in Section 5.2). Protein molecular masses can be determined precisely by a simple calculation based on knowledge of their amino acid sequence, which is often available in genome databases. No simple generalizations correlate the size of proteins with their functions. For instance, the same function may be fulfilled in different cells by proteins of different molecular weight. The *Escherichia coli* enzyme responsible for glutamine synthesis (a protein known as *glutamine synthetase*) has a molecular weight of 600,000, whereas the analogous enzyme in brain tissue has a molecular weight of 380,000.

Foundational Biochemistry Things You Should Know after Reading Chapter 4.

- The common amino acids contain a central α -carbon covalently linked to an amino group, a carboxyl group, a hydrogen, and a side chain, also known as an R group.
- The amino group of one amino acid and the carboxyl group of another amino acid can link together covalently to form an amide bond, also termed a peptide bond.
- The nonpolar amino acids include alanine, isoleucine, leucine, methionine, phenylalanine, proline, tryptophan, and valine.
- The polar, uncharged amino acids include asparagine, cysteine, glutamine, glycine, serine, threonine, and tyrosine.
- The acidic amino acids include aspartic acid and glutamic acid.
- The basic amino acids include arginine, histidine, and lysine.
- The common amino acids are referred to in proteins by their three-letter and one-letter codes.
- Amino acids that occur less commonly in proteins include selenocysteine, hydroxylysine, γ -carboxyglutamate, and pyroglutamate.
- The pK_a values of the α -carboxyl groups in amino acids are approximately 2.
- The pK_a values of the α -amino groups in amino acids are approximately 9.
- The pK_a values of the side chains in amino acids are 3.9, 4.3, 6.0, 8.3, 10.1, 10.5, 12.5, 13, and 13 for Asp, Glu, His, Cys, Tyr, Lys, Arg, Ser, and Thr, respectively.
- The α -amino groups of amino acids react with phenylisothiocyanate (Edman's reagent) to form PTH derivatives.
- All the common amino acids are chiral molecules. All the amino acids in natural proteins are of the L-configuration.
- Phenylalanine, tyrosine, and tryptophan absorb ultraviolet radiation. Absorbance at 280 nm due to tyrosine and tryptophan is diagnostic for the presence of protein in an unknown solution and can be used to estimate the concentration of protein.
- Amino acids can be characterized with NMR spectroscopy. Multidimensional NMR studies can be used to determine the structures of peptides and proteins in solution.
- Mixtures of amino acids can be separated and characterized using various chromatography methods.
- Proteins are unbranched polymers of amino acids linked head-to-tail through the formation of peptide bonds.
- The peptide bond has approximately 40% double-bond character.
- The six atoms comprising the peptide bond group are coplanar and form the so-called peptide plane.
- Peptides consisting of 20 or so amino acids are termed oligopeptides. Longer peptides are termed polypeptides.
- The polypeptide backbone is relatively polar.
- Proteins with one polypeptide chain are monomeric proteins. Proteins composed of more than one polypeptide chain are multimeric proteins.
- Multimeric proteins composed of only one kind of polypeptide are homomultimers. Proteins composed of two or more different polypeptides are heteromultimers.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Drawing Fischer Projection Formulas for Amino Acids** Without consulting chapter figures, draw Fischer projection formulas for glycine, aspartate, leucine, isoleucine, methionine, and threonine.
- Knowing Abbreviations for Amino Acids** Without reference to the text, give the one-letter and three-letter abbreviations for asparagine, arginine, cysteine, lysine, proline, tyrosine, and tryptophan.
- Recognizing Peptide Structures** Consider the peptide structures shown and give the sequence of amino acids (from N-terminal to C-terminal) in these peptides.

- Recognizing Zwitterions** Consider the structure shown.
 - Would you consider this a zwitterion or not? Explain.
 - If not, would the pH have to increase or decrease to make it a zwitterion? Explain.

- Writing Dissociation Equations for Amino Acids** Write equations for the ionic dissociations of alanine, glutamate, histidine, lysine, and phenylalanine.

- Understanding Chemical Effects on Amino Acid pK_a Values** How is the pK_a of the α - NH_3^+ group affected by the presence on an amino acid of the α - COO^- ?

- pH and Charges in Amino Acid Side Chains** Consider the structure of histidine shown in Figure 4.3. One of the two nitrogen atoms in the side chain can act as a proton donor/acceptor and the pK_a value has been determined as 6.0.
 - Draw a titration curve for histidine.
 - Using the Henderson-Hasselbalch equation from Chapter 2, calculate the ratio of the charged and uncharged states of the side chain of histidine at pH 7.4.

- Drawing Titration Curves for the Amino Acids** (Integrates with Chapter 2.) Draw an appropriate titration curve for aspartic acid, labeling the axes and indicating the equivalence points and the pK_a values.

- Calculating Concentrations of Species in Amino Acid Solutions** (Integrates with Chapter 2.) Calculate the concentrations of all ionic species in a 0.25 M solution of histidine at pH 2, pH 6.4, and pH 9.3.

- Calculating pH in Amino Acid Solutions I** (Integrates with Chapter 2.) Calculate the pH at which the γ -carboxyl group of glutamic acid is two-thirds dissociated.

- Calculating pH in Amino Acid Solutions II** (Integrates with Chapter 2.) Calculate the pH at which the ϵ -amino group of lysine is 20% dissociated.

- Calculating pH in Amino Acid Solutions III** (Integrates with Chapter 2.) Calculate the pH of a 0.3 M solution of (a) valine hydrochloride, (b) sodium valinate, and (c) isoelectric valine.

- Understanding Stereochemical Transformations of Amino Acids** Absolute configurations of the amino acids are referenced to D- and L-glyceraldehyde on the basis of chemical transformations that can convert the molecule of interest to either of these reference isomeric structures. In such reactions, the stereochemical consequences for the asymmetric centers must be understood for each reaction step. Propose a sequence of reactions that would demonstrate that L(-)-serine is stereochemically related to L(-)-glyceraldehyde.

- Understanding Amino Acid Stereochemistry** Describe the stereochemical aspects of the structure of cystine, the structure that is a disulfide-linked pair of cysteines.

- Amino Acids and Stereochemistry** The genetic code is a system in which each amino acid in a protein is determined by the sequence of nucleotides in DNA. Our genome codes for the 20 amino acids considered in this chapter. If we used all possible isoforms (stereoisomers) for each amino acid, how many amino acids would need to be encoded in our genome in total?

- Understanding Amino Acid Reaction Mechanisms** Draw a simple mechanism for the reaction of a cysteine sulfhydryl group with iodoacetamide.

- Determining Tyrosine Content of an Unknown Protein** A previously unknown protein has been isolated in your laboratory. Others in your lab have determined that the protein sequence contains 172 amino acids. They have also determined that this protein has no tryptophan and no phenylalanine. You have been asked to determine the possible tyrosine content of this protein. You know from your study of this chapter that there is a relatively easy way to do this. You prepare a pure 50 mM solution of the protein, and you place it in a sample cell with a 1-cm path length, and you measure the absorbance of this sample at 280 nm in a UV-visible spectrophotometer. The absorbance of the solution is 0.372. Are there tyrosines in this protein? How many? (*Hint:* You will need to use Beer's law, which is described in any good general chemistry or physical chemistry textbook. You will also find it useful to know that the units of **molar absorptivity** are $M^{-1}cm^{-1}$.)

18. A Rule of Thumb for Amino Acid Content in Proteins The simple average molecular weight of the 20 common amino acids is 138, but most biochemists use 110 when estimating the number of amino acids in a protein of known molecular weight. Why do you suppose this is? (*Hint:* There are two contributing factors to the answer. One of them will be apparent from a brief consideration of the amino acid compositions of common proteins. See, for example, Figure 5.16 of this text.)

19. Understanding the Chemistry of the Dipeptide Sweetener Aspartame The artificial sweeteners Equal and NutraSweet contain aspartame, which has the structure:

What are the two amino acids that are components of aspartame? What kind of bond links these amino acids? What do you suppose might happen if a solution of aspartame was heated for several hours at a pH near neutrality? Suppose you wanted to make hot chocolate sweetened only with aspartame, and you stored it in a thermos for several hours before drinking it. What might it taste like?

20. Understanding a Defect of Amino Acid Metabolism Individuals with phenylketonuria must avoid dietary phenylalanine because they are unable to convert phenylalanine to tyrosine. Look up this condition and find out what happens if phenylalanine accumulates in the body. Would you advise a person with phenylketonuria to consume foods sweetened with aspartame? Why or why not?

21. Distinguishing Prochiral Isomers In this chapter, the concept of prochirality was discussed. Citrate (see Figure 19.2) is a prochiral molecule. Describe the process by which you would distinguish between the (R-) and (S-) portions of this molecule and how an enzyme could discriminate between similar but distinct moieties.

22. Understanding Buffer Capacity of Amino Acids Amino acids are frequently used as buffers. Describe the pH range of acceptable buffering behavior for the amino acids alanine, histidine, aspartic acid, and lysine.

23. Determining Absolute Configuration in Amino Acids The different isomeric forms of chiral molecules are remarkably similar in their structures and physical properties. How can the different isomeric forms be characterized and distinguished? Consult suitable references to learn about the work of Jean-Baptiste Biot and Louis Pasteur that first revealed evidence for “optical activity.” Read also about the work of Emil Fischer that came very close to determining the correct structure of natural glucose. Finally, look up the work of J. M. Bijvoet that confirmed Emil Fischer’s determination of the structure of glucose.

24. The Origin of D,L Nomenclature Some chemists and biochemists mistakenly attribute the system of D,L nomenclature to Emil Fischer. Consult suitable reference works to learn who actually devised the D,L system for naming chiral molecules.

25. The Advantage of Replacing Cysteine with Selenocysteine in a Redox Enzyme More than a hundred types of selenocysteine-containing

proteins have been characterized. One of these is the enzyme named methionine-S-sulfoxide reductase. In several of these, the replacement of cysteine with selenocysteine confers a catalytic advantage to the enzyme. What is the chemical basis for this catalytic advantage? Consult a suitable reference to explain how this works. (one good reference: Kim, H.-Y., Fomenko, D. E., Yoon, Y.-E., and Gladyshev, V. N., 2006. *Biochemistry* **45**:13697–13704.)

26. The Murchison Meteorite—a Possible Explanation for L-Isomer Predominance in Earthly Amino Acids The predominance of L-amino acids in biological systems is one of life’s intriguing features. Hints as to the origins of this preference have come to Earth in the form of meteorites that contain enantiomeric excesses of particular amino acids. One of these is the famous Murchison meteorite that fell in Murchison, Australia in 1969, but many others have now also been studied. Consult suitable references to learn more about these events and their analysis and summarize what is known about enantiomeric preferences in interstellar objects such as meteorites. (Good references: Elsila, J. E., et al., 2016. Meteoric amino acids: diversity in compositions reflects parent body histories. *ACS Central Science* **2**:370–379; Pizzarello, S., 2006. The chemistry of life’s origin: a carbonaceous meteorite perspective. *Accounts of Chemical Research* **39**:231–237; Schmitt-Kopplin, P., et al., 2011. High molecular diversity of extraterrestrial organic matter in Murchison meteorite revealed 40 years after its fall. *Proceedings of the National Academy of Sciences, USA* **107**:2763–2768.)

27. Although the other common amino acids are used as buffers, cysteine is rarely used for this purpose. Why?

28. Draw all the possible isomers of threonine and assign (R,S) nomenclature to each.

Think-Pair-Share Question

Amino Acid Analysis Using RP-HPLC A student was tasked with the development of a new chromatography protocol to analyze amino acids (see Section 4.6a). The student was asked to evaluate the protocol by analyzing all twenty amino acids at least twice. Faced with the prospect of having to perform forty analyses, the student took a “combinatorial” approach to the request. The results of the combinatorial approach as applied to nine different amino acids is shown below. Six mixtures were prepared containing three different amino acids and analyzed. The mixtures and the observed retention times are listed in the table.

Mixture	Amino acids present			Retention times (min)		
I	Phe	Asp	Pro	1.08	2.78	3.82
II	Met	Lys	Ser	2.29	3.46	4.46
III	Ala	Val	Leu	2.89	3.33	3.67
IV	Val	Asp	Lys	1.11	3.35	3.67
V	Pro	Ser	Leu	2.31	2.79	3.68
VI	Met	Phe	Ala	2.91	3.47	3.83

For each mixture the retention times cannot be assigned to any individual amino acid present. However, the student claims that the six analyses resulted in a duplicate estimate of each amino acid’s retention time. With a fellow student, determine how this system works and what the retention time results were for each amino acid.

◀ Helices, which sometimes appear as decorative or utilitarian motifs in manmade structures, are a common structural theme in biological macromolecules—proteins, nucleic acids, and even polysaccharides.

Essential Questions

Proteins are polymers composed of hundreds or even thousands of amino acids linked in series by peptide bonds. **What structural forms do these polypeptide chains assume, how can the sequence of amino acids in a protein be determined, and what are the biological roles played by proteins?**

Proteins are a diverse and abundant class of biomolecules, making up more than 50% of the dry weight of cells. Their diversity and abundance reflect the central role of proteins in virtually all aspects of cell structure and function. An extraordinary repertoire of cellular activity is possible only because of the versatility inherent in proteins, each of which is specifically tailored to its biological role. The pattern by which each is tailored resides within the genetic information of cells, encoded in a specific sequence of nucleotide bases in DNA. Each such segment of encoded information defines a gene, and expression of the gene leads to synthesis of the specific protein encoded by it, endowing the cell with the functions unique to that particular protein. Proteins are the agents of biological function; they are also the expressions of genetic information.

5.1 | What Architectural Arrangements Characterize Protein Structure?

Proteins are among the most complex molecular structures known. How can their structural properties be dissected and understood? First, protein structures can be classified according to their overall shape and solubility. Then, deeper inspection reveals that protein structures can be described by organizational patterns based on the amino acid sequence of their polypeptide chains and on how noncovalent interactions lead these chains to fold into unique three-dimensional architectures.

Key Questions

- 5.1 What Architectural Arrangements Characterize Protein Structure?
- 5.2 How Are Proteins Isolated and Purified from Cells?
- 5.3 How Is the Primary Structure of a Protein Determined?
- 5.4 What Is the Nature of Amino Acid Sequences?
- 5.5 Can Polypeptides Be Synthesized in the Laboratory?
- 5.6 Do Proteins Have Chemical Groups Other Than Amino Acids?
- 5.7 What Are the Many Biological Functions of Proteins?
- 5.8 What Is the Proteome and What Does It Tell Us?

Figure 5.1 Three classes of proteins. **(a)** Collagen, a major component of animal connective tissue, is the most abundant protein in mammals. Proteins having structural roles in cells are typically fibrous and often water insoluble. **(b)** Myoglobin is a globular protein. **(c)** Membrane proteins fold so that hydrophobic amino acid side chains are exposed in their membrane-associated regions. Bacteriorhodopsin binds the light-absorbing pigment, *cis*-retinal, shown here in blue.

5.1a Proteins Fall into Three Basic Classes According to Shape and Solubility

As a first approximation, proteins can be assigned to one of three global classes on the basis of shape and solubility: fibrous, globular, or membrane (Figure 5.1). **Fibrous proteins** tend to have relatively simple, regular linear structures. These proteins often serve structural roles in cells. Typically, they are insoluble in water or in dilute salt solutions. In contrast, **globular proteins** are roughly spherical in shape. The polypeptide chain is compactly folded so that hydrophobic amino acid side chains are in the interior of the molecule and the hydrophilic side chains are on the outside exposed to the solvent, water. Consequently, globular proteins are usually very soluble in aqueous solutions. Most soluble proteins of the cell, such as the cytosolic enzymes, are globular in shape. **Membrane proteins** are found in association with the various membrane systems of cells. For interaction with the nonpolar phase within membranes,

Careers in Chemistry

Lilla Marton

Lilla Marton teaches biochemistry to young women of Abu Dhabi attending the Sheikh Zayed Private Academy. Lilla was an undergraduate biology major at the University of South Carolina, and she stayed there to earn her M.S. in teaching. Marton's parents were first-generation immigrants to the USA from the city of Szeged in Hungary. When Lilla was young, her father, a plant biotechnologist, would tell her fairy tales about photosynthesis instead of princesses. Her experiences growing

up with English as a second language and being instilled with the love of science from her family are important to her relationship with teaching and the science of biology. Lilla's background makes her especially attuned to the needs of young women who speak English as a non-primary language. She delights in sharing her love of science with anyone who wants to learn, regardless of the barriers presented.

membrane proteins have hydrophobic amino acid side chains oriented outward. As such, membrane proteins are insoluble in aqueous solutions but can be solubilized in solutions of detergents. Membrane proteins characteristically have fewer hydrophilic amino acids than cytosolic proteins.

5.1b Protein Structure Is Described in Terms of Four Levels of Organization

The architecture of protein molecules is quite complex. Nevertheless, this complexity can be resolved by defining various levels of structural organization.

Primary Structure The amino acid sequence is, by definition, the **primary (1°) structure** of a protein. For example, the primary structure of bovine pancreatic RNase is shown in Figure 5.2. The amino acid sequence of a protein is its defining feature. All other structural properties, as well as the protein's function, follow from its primary structure.

Secondary Structure Through hydrogen-bonding interactions between adjacent amino acid residues, the polypeptide chain can arrange itself into characteristic helical or pleated segments. These segments constitute structural conformities, so-called **regular structures**, which extend along one dimension, like the coils of a spring. Such architectural features of a protein are designated **secondary (2°) structures** (Figure 5.3). Secondary structures are just one of the higher levels of structure that represent the three-dimensional arrangement of the polypeptide in space.

α -Helix
Only the N — C $_{\alpha}$ — C backbone is represented. The vertical line is the helix axis.

β -Strand
The N — C $_{\alpha}$ — C backbone as well as the C $_{\beta}$ of R groups are represented here. Note that the amide planes are perpendicular to the page.

Symbolic representation of an α -helix

Symbolic representation of a β -strand

Figure 5.3 The α -helix and the β -pleated strand are the two principal secondary structures found in proteins. Simple representations of these structures are a flat, helical ribbon or a cylinder for the α -helix and a flat, wide arrow for β -structures.

(a) Chymotrypsin tertiary structure

(b)

Chymotrypsin ribbon

(c)

Chymotrypsin space-filling model

Figure 5.4 Folding of the polypeptide chain into a compact, roughly spherical conformation creates the tertiary level of protein structure. Shown here are three different representations of the tertiary structure of the protein chymotrypsin: (a) A tracing showing the position of all of the C $_{\alpha}$ carbon atoms, (b) a ribbon diagram that shows the three-dimensional track of the polypeptide chain, and (c) a space-filling representation of the atoms as spheres.

Tertiary Structure When the polypeptide chains of protein molecules bend and fold in order to assume a more compact three-dimensional shape, the **tertiary (3°) level of structure** is generated (Figure 5.4). It is by virtue of their tertiary structure that proteins adopt a globular shape. A globular conformation gives the lowest surface-to-volume ratio, minimizing interaction of the protein with the surrounding environment.

Quaternary Structure Many proteins consist of two or more interacting polypeptide chains of characteristic tertiary structure, each of which is commonly referred to as a **subunit** of the protein. Subunit organization constitutes another level in the hierarchy of protein structure, defined as the protein's **quaternary (4°) structure** (Figure 5.5). The protein's quaternary structure includes the various kinds of subunits within a protein molecule, the number of each, and the ways in which they interact with one another.

5.1c Noncovalent Forces Drive Formation of the Higher Orders of Protein Structure

Whereas the primary structure of a protein is determined by the covalently linked amino acid residues in the polypeptide backbone, secondary and higher orders of structure are determined principally by noncovalent forces such as hydrogen bonds as well as ionic, van der Waals, and hydrophobic interactions. It is important to emphasize that *all the information necessary for a protein molecule to achieve its intricate architecture is contained within its 1° structure*, that is, within the amino acid sequence of its polypeptide chain(s).

5.1d A Protein's Conformation Can Be Described as Its Overall Three-Dimensional Structure

The overall three-dimensional architecture of a protein is generally referred to as its **conformation**. This term is not to be confused with **configuration**, which denotes the geometric possibilities for a particular set of atoms (Figure 5.6). In going from one configuration to another, covalent bonds must be broken and rearranged.

Figure 5.5 Hemoglobin is a tetramer consisting of two α and two β polypeptide chains.

In contrast, the *conformational possibilities* of a molecule are achieved without breaking any covalent bonds. In proteins, rotations about each of the single bonds along the peptide backbone have the potential to alter the course of the polypeptide chain in three-dimensional space. These rotational possibilities create many possible orientations for the protein chain, referred to as its conformational possibilities. Of the great number of theoretical conformations a given protein might adopt, only a very few are favored energetically under physiological conditions. At this time, the rules that direct the folding of protein chains into energetically favorable conformations are still not entirely clear; accordingly, they are the subject of intensive contemporary research. Chapter 6 presents a detailed discussion of the 2°, 3°, and 4° structure of protein molecules.

5.2 | How Are Proteins Isolated and Purified from Cells?

Cells contain thousands of different proteins. The first step in studying a specific protein is to purify it, so it is not contaminated by the presence of any other proteins. Because the biological function of a protein depends on its native (occasionally called physiological) structure, techniques employed in protein purification should not denature the protein (Figure 1.17). The starting material for protein purification is usually a cell type or tissue of interest; alternatively, cloned cells engineered to mass produce the protein are used. Proteins can be separated and purified on the basis of their two prominent physical properties: size and electrical charge. A direct approach is to use **affinity purification** strategies that take advantage of the ligand-binding properties of a protein (see A Deeper Look box: Techniques Used in Protein Purification).

5.2a A Number of Protein Separation Methods Exploit Differences in Size and Charge

Separation methods based on size include size exclusion chromatography, ultrafiltration, and ultracentrifugation (see A Deeper Look box: Techniques Used in Protein Purification). The charge or ionic properties of peptides and proteins are determined principally by their complement of amino acid side chains. Furthermore, the ionization of these groups is pH dependent.

A variety of procedures has been designed to exploit the electrical charges on a protein as a means to separate proteins in a mixture. These procedures include ion exchange chromatography, electrophoresis (see A Deeper Look box: Techniques Used in Protein Purification), and separation by solubility. Proteins tend to be least soluble at their **isoelectric point**, the pH value at which the sum of their positive and negative electrical charges is zero. At this pH, electrostatic repulsion between protein molecules is minimal and they are more likely to coalesce and precipitate out of solution. Ionic strength also profoundly influences protein solubility. Most globular proteins tend to become increasingly soluble as the ionic strength is raised. This phenomenon, the **salting-in** of proteins, is attributed to the diminishment of electrostatic attractions between protein molecules by the presence of abundant salt ions. Such electrostatic interactions between the protein molecules would otherwise lead to precipitation. However, as the salt concentration reaches high levels (greater than 1 M), the effect may reverse so that the protein is salted out of solution. In such cases, the numerous salt ions begin to compete with the protein for waters of solvation, and as they win out, the protein becomes insoluble. The solubility properties of a typical protein are shown in Figure 5.7.

Although the side chains of nonpolar amino acids in soluble proteins are usually buried in the interior of the protein away from contact with the aqueous solvent, a portion of them may be exposed at the protein's surface, giving it a partially hydrophobic character. Hydrophobic interaction chromatography is a protein purification technique that exploits this hydrophobicity (see A Deeper Look box: Techniques Used in Protein Purification).

Figure 5.7 The solubility of most globular proteins is markedly influenced by pH and ionic strength. This figure shows the solubility of a typical protein as a function of pH and various salt concentrations.

A Deeper Look

Estimation of Protein Concentrations in Solutions of Biological Origin

Biochemists are often interested in knowing the protein concentration in various preparations of biological origin. Such quantitative analysis is not straightforward. Cell extracts are complex mixtures that typically contain protein molecules of many different molecular weights, so the results of protein estimations cannot be expressed on a molar basis. Also, aside from the rather unreactive repeating peptide backbone, little common chemical identity is seen among the many proteins found in cells that might be readily exploited for exact chemical analysis. Most of their chemical properties vary with their amino acid composition, for example, nitrogen or sulfur content or the presence of aromatic, hydroxyl, or other functional groups.

Several methods rely on the reduction of Cu^{2+} ions to Cu^+ by readily oxidizable protein components, such as cysteine or the phenols and indoles of tyrosine and tryptophan. For example, *bicinchoninic acid* (BCA) forms a purple complex with Cu^+ in alkaline solution, and the amount of Cu^+ formed upon the reaction of a protein sample with Cu^{2+} can be easily measured spectrophotometrically to provide an estimate of protein concentration.

Other assays are based on dye binding by proteins. The Bradford assay is a rapid and reliable technique that uses a dye called *Coomassie*

Brilliant Blue G-250, which undergoes a change in its color upon binding to proteins. The binding is quantitative and takes place through hydrophobic interactions as well as ionic bonding with basic amino groups. The color change is easily measured by a spectrophotometer. A similar, very sensitive method capable of quantifying nanogram amounts of protein is based on the shift in color of colloidal gold upon binding to proteins.

5.2b A Typical Protein Purification Scheme Uses a Series of Separation Methods

Most purification procedures for a particular protein are developed in an empirical manner, the overriding aim being isolation of the protein in a pure state with acceptable yield. The source material is harvested cells, an organ, or an entire organism thought to contain the protein of interest. The first step is to break open the cells so that the protein can be extracted. Table 5.1 presents a summary of a purification scheme for a desired enzyme. Note that the **specific activity** of the enzyme in the immunoaffinity purified fraction (fraction 5) has been increased 152/0.108, or 1407 times the specific activity in the crude extract (fraction 1). Thus, the concentration of this protein has been enriched more than 1400-fold by the purification procedure.

Table 5.1 Example of a Protein Purification Scheme: Purification of an Enzyme from a Cell Extract

Fraction	Volume (mL)	Total Protein (mg)	Total Activity*	Specific Activity†	Percent Recovery‡
1. Crude extract	3800	22,800	2460	0.108	100
2. Salt precipitate	165	2800	1190	0.425	48
3. Ion exchange chromatography	65	100	720	7.2	29
4. Molecular sieve chromatography	40	14.5	555	38.3	23
5. Immunoaffinity chromatography§	6	1.8	275	152	11

*The relative enzymatic activity of each fraction is cited as arbitrarily defined units. One unit here is 1 nanomole/mL of substrate converted per minute. The enzyme is xanthine dehydrogenase from the bread mold *Neurospora crassa*.

†The specific activity is the total activity of the fraction divided by the total protein in the fraction. This value gives an indication of the increase in purity attained during the course of the purification as the samples become enriched for the enzyme.

‡The percent recovery of total activity is a measure of the yield of the desired enzyme.

§The last step in the procedure is an affinity method in which antibodies specific for the enzyme are covalently coupled to a chromatography matrix and packed into a glass tube to make a chromatographic column through which fraction 4 is passed. The enzyme is bound by this immunoaffinity matrix while other proteins pass freely out. The enzyme is then recovered by passing through the column a strong salt solution, which dissociates the enzyme-antibody complex.

Techniques Used in Protein Purification¹

Dialysis and Ultrafiltration

If a solution of protein is separated from a bathing solution by a semipermeable membrane, small molecules and ions can pass through the semipermeable membrane to equilibrate between the protein solution and the bathing solution, called the *dialysis bath* or *dialysate* (Figure 1). This method is useful for removing small molecules from macromolecular solutions or for altering the composition of the protein-containing solution.

Ultrafiltration is an improvement on the dialysis principle. Filters with pore sizes over the range of biomolecular dimensions are used to filter solutions to select for molecules in a particular size range. Because the pore sizes in these filters are microscopic, high pressures are often required to force the solution through the filter. This technique is useful for concentrating dilute solutions of macromolecules. The concentrated protein can then be diluted into the solution of choice.

Ion Exchange Chromatography Can Be Used to Separate Molecules on the Basis of Charge

Charged molecules can be separated using *ion exchange chromatography*, a process in which the charged molecules of interest (*ions*) are *exchanged* for another ion (usually a salt ion) on a charged solid support. In a typical procedure, solutes in a liquid phase, usually water, are passed through a column filled with a porous solid phase composed of synthetic resin particles containing charged groups. Resins containing positively charged groups attract negatively charged solutes and are referred to as *anion exchange resins*. Resins with negatively charged groups are *cation exchangers*. Weakly acidic or basic groups on ion exchange resins exhibit charges that are dependent on

the pH of the bathing solution. Changing the pH will alter the ionic interaction between the resin groups and the bound ions. In all cases, the bare charges on the resin particles must be counterbalanced by oppositely charged ions in solution (*counterions*); salt ions (e.g., Na^+ or Cl^-) usually serve this purpose. The hypothetical separation of a mixture of several proteins on a column of cation exchange resin is illustrated in Figure 2. Increasing the salt concentration in the solution passing through the column leads to competition between the cationic proteins bound to the column and the cations in the salt for binding to the column. Bound cationic proteins that interact weakly with the charged groups on the resin wash out first, and those interacting strongly are washed out only at high salt concentrations.

Figure 1 A dialysis experiment. The solution of macromolecules to be dialyzed is placed in a semipermeable membrane bag, and the bag is immersed in a bathing solution. A magnetic stirrer gently mixes the solution to facilitate equilibrium of diffusible solutes between the dialysate and the solution contained in the bag.

¹Although this box is titled *Techniques Used in Protein Purification*, these methods are also applicable to other macromolecules such as nucleic acids.

Figure 2 The separation of proteins on a cation exchange column.

Size Exclusion Chromatography

Size exclusion chromatography is also known as *gel filtration chromatography* or *molecular sieve chromatography*. In this method, fine, porous beads are packed into a chromatography column. The pore sizes of these beads approximate the dimensions of macromolecules. The total bed volume (Figure 3) of the packed chromatography column, V_t , is equal to the volume outside the porous beads (V_o) plus the volume inside the beads (V_i) plus the volume actually occupied by the bead material (V_g): $V_t = V_o + V_i + V_g$. (V_g is typically less than 1% of V_t and can be conveniently ignored in most applications.)

As a solution of molecules is passed through the column, the molecules passively distribute between V_o and V_i , depending on their ability to enter the pores (that is, their size). If a molecule is too large to enter at all, it is totally excluded from V_i and emerges first from the column at an elution volume, V_e , equal to V_o . If a particular molecule can enter the pores in the gel, its distribution is given by the *distribution coefficient*, K_D :

$$K_D = (V_e - V_o) / V_i$$

where V_e is the molecule's characteristic elution volume. The chromatography run is complete when a volume of solvent equal to V_t has passed through the column.

Electrophoresis

Electrophoretic techniques are based on the movement of ions in an electrical field. An ion of charge q experiences a force F given by $F = Eqd$, where E is the voltage (or *electrical potential*) and d is the distance between the electrodes. In a vacuum, F would cause the molecule to accelerate. In solution, the molecule experiences *frictional drag*, F_f , due to the solvent:

$$F_f = 6\pi r\eta v$$

where r is the radius of the charged molecule, η is the viscosity of the solution, and v is the velocity at which the charged molecule is moving. So, the velocity of the charged molecule is proportional to its charge q and the voltage E , but inversely proportional to the viscosity of the medium η and d , the distance between the electrodes.

Generally, electrophoresis is carried out *not* in free solution but in a porous support matrix such as polyacrylamide or agarose, which slows the movement of molecules according to their dimensions relative to the size of the pores in the matrix.

SDS-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

SDS is sodium dodecylsulfate (sodium lauryl sulfate) (Figure 4). The hydrophobic tail of dodecylsulfate interacts strongly with polypeptide chains. The number of SDS molecules bound by a polypeptide is proportional to the length (number of amino acid residues) of the polypeptide. Each dodecylsulfate contributes two negative charges. Collectively, these charges overwhelm any intrinsic charge that the protein might have. SDS is also a detergent that disrupts protein folding (protein 3° structure). SDS-PAGE is usually run in the presence of sulfhydryl-reducing agents such as β -mercaptoethanol so that any disulfide links between polypeptide chains are broken. The electrophoretic mobility of proteins upon SDS-PAGE is inversely proportional to the logarithm of the protein's molecular weight (Figure 5). SDS-PAGE is often used to determine the molecular weight of a polypeptide chain.

Isoelectric Focusing

Isoelectric focusing is an electrophoretic technique for separating proteins according to their *isoelectric points* (pIs). A solution of *ampholytes* (amphoteric electrolytes) is first electrophoresed through a gel, usually contained in a small tube. The migration of these substances in an electric field establishes a pH gradient in the tube. Then a protein mixture is applied to the gel, and electrophoresis is resumed. As the protein molecules move down the gel, they experience the pH gradient and migrate to a position corresponding to their respective pIs. At its pI, a protein has no net charge and thus moves no farther.

Figure 3 Gel filtration separates proteins according to size. (a) A gel filtration chromatography column. Larger molecules are excluded from the gel beads and emerge from the column sooner than smaller molecules, whose migration is slowed because they can enter the beads. (b) An elution profile.

Figure 4 The structure of sodium dodecylsulfate (SDS).

Figure 5 A plot of the relative electrophoretic mobility of proteins in SDS-PAGE versus the log of the molecular weights of the individual polypeptides.

(Continued)

Two-Dimensional Gel Electrophoresis

This separation technique uses isoelectric focusing in one dimension and SDS-PAGE in the second dimension to resolve protein mixtures. The proteins in a mixture are first separated according to pI by isoelectric focusing in a polyacrylamide gel in a tube. The gel is then removed and laid along the top of an SDS-PAGE slab, and the proteins are electrophoresed into the SDS polyacrylamide gel, where they are separated according to size (Figure 6). The gel slab can then be stained to reveal the locations of the individual proteins. Using this powerful technique, researchers have the potential to visualize and construct catalogs of virtually *all* the proteins present in particular cell types. The **ExPASy** server at <http://us.expasy.org> provides access to a two-dimensional polyacrylamide gel electrophoresis database named **SWISS-2DPAGE**. This database contains information on proteins, identified as spots on two-dimensional electrophoresis gels, from many different cell and tissue types.

Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography (HIC) exploits the hydrophobic nature of proteins in purifying them. Proteins are passed over a chromatographic column packed with a support matrix to which

hydrophobic groups are covalently linked. *Phenyl Sepharose*, an agarose support matrix to which phenyl groups are attached, is a prime example of such material. In the presence of high salt concentrations, proteins bind to the phenyl groups by virtue of hydrophobic interactions. Proteins in a mixture can be differentially eluted from the phenyl groups by lowering the salt concentration or by adding solvents such as polyethylene glycol to the elution fluid.

High-Performance Liquid Chromatography

The principles exploited in *high-performance* (or high-pressure) *liquid chromatography* (HPLC) are the same as those used in the common chromatographic methods such as ion exchange chromatography or size exclusion chromatography. Very-high-resolution separations can be achieved quickly and with high sensitivity in HPLC using automated instrumentation. *Reverse-phase* HPLC is a widely used chromatographic procedure for the separation of nonpolar solutes. In reverse-phase HPLC, a solution of nonpolar solutes is chromatographed on a column having a nonpolar liquid immobilized on an inert matrix; this nonpolar liquid serves as the *stationary phase*. A more polar liquid that serves as the *mobile phase* is passed over the matrix, and solute molecules are eluted in proportion to their solubility in this more polar liquid.

Figure 6 A two-dimensional electrophoresis separation. A mixture of macromolecules is first separated according to charge by isoelectric focusing in a tube gel. The gel containing separated molecules is then placed on top of an SDS-PAGE slab, and the molecules are electrophoresed into the SDS-PAGE gel, where they are separated according to size. Shown on the right is an actual 2D-gel electrophoretogram of mouse liver proteins from the Swiss Institute of Bioinformatics database.

Affinity Chromatography

Affinity purification strategies for proteins exploit the biological function of the target protein. In most instances, proteins carry out their biological activity through binding or complex formation with specific small biomolecules, or *ligands*, as in the case of an enzyme binding its substrate. If this small molecule can be immobilized through covalent attachment to an insoluble matrix, such as a chromatographic medium like cellulose or polyacrylamide, then the protein of interest, in displaying affinity for its ligand, becomes bound and immobilized itself. It can then be removed from contaminating proteins in the mixture by simple means such as filtration and washing the matrix. Finally, the protein is dissociated or eluted from the matrix by the addition of high concentrations of the free ligand in solution. Figure 7 depicts the protocol for such an *affinity chromatography* scheme. Because this method of purification relies on the biological specificity of the protein of interest, it is a very efficient procedure, and proteins can be purified several thousand-fold in a single step.

Ultracentrifugation

Centrifugation methods separate macromolecules on the basis of their characteristic densities. Particles tend to “fall” through a solution if the density of the solution is less than the density of the particle. The velocity of the particle through the medium is proportional to the difference in density between the particle and the solution. The tendency of any particle to move through a solution under centrifugal force is given by the *sedimentation coefficient*, S :

$$S = (\rho_p - \rho_m)V/f$$

where ρ_p is the density of the particle or macromolecule, ρ_m is the density of the medium or solution, V is the volume of the particle, and f is the frictional coefficient, given by

$$f = F_f/v$$

where v is the velocity of the particle and F_f is the frictional drag. Nonspherical molecules have larger frictional coefficients and thus smaller sedimentation coefficients. The smaller the particle and the more its shape deviates from spherical, the more slowly that particle sediments in a centrifuge.

Centrifugation can be used either as a preparative technique for separating and purifying macromolecules and cellular components (see Figure 17.16) or as an analytical technique to characterize the hydrodynamic properties of macromolecules such as proteins and nucleic acids. See also the A Deeper Look box: The Buoyant Density of DNA in Section 11.3.

A protein interacts with a metabolite. The metabolite is thus a ligand that binds specifically to this protein

The metabolite can be immobilized by covalently coupling it to an insoluble matrix such as an agarose polymer. Cell extracts containing many individual proteins may be passed through the matrix.

Specific protein binds to ligand. All other unbound material is washed out of the matrix.

Adding an excess of free metabolite that will compete for the bound protein dissociates the protein from the chromatographic matrix. The protein passes out of the column complexed with metabolite.

Purifications of proteins as much as 1,000-fold or more are routinely achieved in a single affinity chromatographic step like this.

5.3 | How Is the Primary Structure of a Protein Determined?

The defining characteristic of each protein is the distinctive sequence of amino acid residues in its polypeptide chain(s). Indeed, it is the **amino acid sequence** of proteins that is encoded by the nucleotide sequence of DNA. This amino acid sequence, then, is a form of genetic information. Because polypeptide chains are unbranched, a polypeptide chain has only two ends, an amino-terminal, or **N-terminal**, end and a carboxy-terminal, or **C-terminal**, end. By convention, the amino acid sequence is read

Figure 5.8 The hormone insulin consists of two polypeptide chains, A and B, held together by two disulfide cross-bridges (S—S). The A chain has 21 amino acid residues and an intrachain disulfide; the B polypeptide contains 30 amino acids. The sequence shown is for bovine insulin.

from the N-terminal end of the polypeptide chain through to the C-terminal end. As an example, every molecule of ribonuclease A from bovine pancreas has the same amino acid sequence, beginning with N-terminal lysine at position 1 and ending with C-terminal valine at position 124 (Figure 5.2). Given the possibility of any of the 20 amino acids at each position, the number of unique amino acid sequences is astronomically large. The astounding sequence variation possible within polypeptide chains provides a key insight into the incredible functional diversity of protein molecules in biological systems discussed later in this chapter.

5.3a Sanger Was the First to Determine the Sequence of a Protein

In 1953, Frederick Sanger of Cambridge University in England reported the amino acid sequences of the two polypeptide chains composing the protein insulin (Figure 5.8). Not only was this a remarkable achievement in analytical chemistry, but it helped demystify speculation about the chemical nature of proteins. Sanger's results clearly established that all of the molecules of a given protein have a defined amino acid sequence, and therefore an invariant molecular weight. In short, proteins are well defined chemically. Today, the amino acid sequences of millions of proteins are known. Although many sequences have been determined from application of the principles first established by Sanger, most are now deduced from knowledge of the nucleotide sequence of the gene that encodes the protein. In addition, in recent years, the application of mass spectrometry to the sequence analysis of proteins has largely superseded the protocols based on chemical and enzymatic degradation of polypeptides that Sanger pioneered. Either mass spectrometry or these chemical and enzymatic protocols are useful in confirming gene sequence data and either can reveal posttranslational modifications of proteins, which often play a critical role in protein function (see Section 5.6).

5.3b Both Chemical and Enzymatic Methodologies Are Used in Protein Sequencing

The chemical strategy for determining the amino acid sequence of a protein involves six basic steps:

1. If the protein contains more than one polypeptide chain, the chains are separated and purified.
2. Intrachain S—S (disulfide) cross-bridges between cysteine residues in the polypeptide chain are cleaved. (If these disulfides are interchain linkages, then step 2 precedes step 1.)
3. The N-terminal and C-terminal residues are identified.
4. Each polypeptide chain is cleaved into smaller fragments, and the amino acid composition and sequence of each fragment are determined.
5. Step 4 is repeated, using a different cleavage procedure to generate a different and therefore overlapping set of peptide fragments.
6. The overall amino acid sequence of the protein is reconstructed from the sequences in overlapping fragments.

Each of these steps is discussed in greater detail in the following sections.

5.3c Step 1. Separation of Polypeptide Chains

If the protein of interest is a **heteromultimer** (composed of more than one type of polypeptide chain), then the protein must be dissociated into its component polypeptide chains, which then must be separated from one another and sequenced individually. Because subunits in multimeric proteins typically associate through noncovalent interactions, most multimeric proteins can be dissociated by exposure to pH extremes, 8 M urea, 6 M guanidinium hydrochloride, or high salt concentrations. (All of these treatments disrupt polar interactions such as hydrogen bonds, both within

A Deeper Look

The Virtually Limitless Number of Different Amino Acid Sequences

Given 20 different amino acids, a polypeptide chain of n residues can have any one of 20^n possible sequence arrangements. To portray this, consider the number of tripeptides possible if there were only three different amino acids, A, B, and C (tripeptide = 3 = n ; $3^n = 3^3 = 27$):

AAA	BBB	CCC
AAB	BBA	CCA
AAC	BBC	CCB
ABA	BAB	CBC
ACA	BCB	CAC
ABC	BAA	CBA
ACB	BCC	CAB
ABB	BAC	CBB
ACC	BCA	CAA

For a polypeptide chain of 100 residues in length, a rather modest size, the number of possible sequences is 20^{100} , or because $20 = 10^{1.3}$, 10^{130} unique possibilities. These numbers are more than astronomical! Because an average protein molecule of 100 residues would have a mass of 12,000 daltons (assuming the average molecular mass of an amino acid residue = 120), 10^{130} such molecules would have a mass of 1.2×10^{134} daltons. The mass of the observable universe is estimated to be 10^{80} proton masses (about 10^{80} daltons). Thus, the universe lacks enough material to make just one molecule of each possible polypeptide sequence for a protein only 100 residues in length.

the protein molecule and between the protein and the aqueous solvent.) Once dissociated, the individual polypeptides can be isolated from one another on the basis of differences in size and/or charge.

5.3d Step 2. Cleavage of Disulfide Bridges

Occasionally, heteromultimers are linked together by interchain S—S bridges. In such instances, these crosslinks must be cleaved before dissociation and isolation of the individual chains. The methods described under step 2 are applicable for this purpose. A number of methods exist for cleaving disulfides. An important consideration is to carry out these cleavages so that the original or even new S—S links do not form. Oxidation of a disulfide by performic acid results in the formation of two equivalents of cysteic acid (Figure 5.9a). Because these cysteic acid side chains are ionized SO_3^- groups, electrostatic repulsion (as well as altered chemistry) prevents S—S recombination. Alternatively, sulfhydryl compounds such as 2-mercaptoethanol or dithiothreitol (DTT) readily reduce S—S bridges to regenerate two cysteine—SH side chains, as in a reversal of the reaction shown in Figure 4.8b. However, these SH groups recombine to re-form either the original disulfide link or, if other free Cys—SHs are available, new disulfide links. To prevent this, S—S reduction must be followed by treatment with alkylating agents such as iodoacetate or 3-bromopropylamine, which modify the SH groups and block disulfide bridge formation (Figure 5.9b).

5.3e Step 3. N- and C-Terminal Analysis

N-Terminal Analysis The amino acid residing at the N-terminal end of a protein can be identified in a number of ways; one method, **Edman degradation**, has become the procedure of choice. This method is preferable because it allows the sequential identification of a series of residues beginning at the N-terminus. In weakly basic solutions, phenylisothiocyanate, or **Edman reagent** (phenyl—N=C=S), combines with the free amino terminus of a protein (see Figure 4.8a), which can be excised from the end of the polypeptide chain and recovered as a PTH derivative. Chromatographic methods can be used to identify this PTH derivative. Importantly, in this procedure, the rest of the polypeptide chain remains intact and can be subjected to further rounds of Edman degradation to identify successive amino acid residues in the chain. Often, the carboxyl terminus of the polypeptide under analysis is coupled to an

(a) Oxidative cleavage

(b) —SH modification

(1)

(2)

Figure 5.9 Methods for cleavage of disulfide bonds in proteins. **(a)** Oxidative cleavage by reaction with performic acid. **(b)** Disulfide bridges can be broken by reduction with sulfhydryl agents such as β -mercaptoethanol or dithiothreitol (as in the reverse of the reaction shown in Figure 4.8b). Because reaction between the newly reduced —SH groups to reestablish disulfide bonds is a likelihood, S—S reduction must be followed by —SH modification: (1) Alkylation with iodoacetate (ICH_2COOH) or (2) modification with 3-bromopropylamine ($\text{Br}-(\text{CH}_2)_3-\text{NH}_2$).

insoluble matrix, allowing the polypeptide to be easily recovered by filtration or centrifugation following each round of Edman reaction. Thus, the Edman reaction not only identifies the N-terminal residue of proteins but through successive reaction cycles can reveal further information about sequence. Automated instruments (so-called Edman sequencers) have been designed to carry out repeated rounds of the Edman procedure. In practical terms, such devices require 3 picomoles (about 6 nanograms) of a polypeptide and yield about 15 residues of sequence information. Today, mass spectrometry, not Edman sequencing, is the preferred way to obtain the amino acid sequence of a protein (see Section 5.3h).

C-Terminal Analysis For the identification of the C-terminal residue of polypeptides, an enzymatic approach is commonly used. Carboxypeptidases are enzymes that cleave amino acid residues from the C-termini of polypeptides in a successive fashion. Several carboxypeptidases are in general use: A, B, and Y (sometimes designated C). *Carboxypeptidase A* (from bovine pancreas) works well in hydrolyzing the C-terminal peptide bond of all residues except proline, aspartate, glutamate, arginine, and lysine. The analogous enzyme from hog pancreas, *carboxypeptidase B*, is effective only when Arg or Lys are the C-terminal residues. *Carboxypeptidase Y* from yeast acts on any C-terminal residue. Because the nature of the amino acid residue at the end often

determines the rate at which it is cleaved and because these enzymes remove residues successively, care must be taken in interpreting results. Carboxypeptidase Y cleavage has been adapted to an automated protocol analogous to that used in Edman sequencers.

5.3f Steps 4 and 5. Fragmentation of the Polypeptide Chain

The aim in these steps is to produce fragments useful for sequence analysis. The cleavage methods employed are usually enzymatic, but proteins can also be fragmented by specific or nonspecific chemical means (such as partial acid hydrolysis). Proteolytic enzymes offer an advantage in that many hydrolyze only specific peptide bonds, and this specificity immediately gives information about the peptide products. As a first approximation, fragments produced upon cleavage should be small enough to yield their sequences through end-group analysis and Edman degradation, yet not so small that an overabundance of products must be resolved before analysis.

Using Proteases to Cleave Protein Chains The digestive enzyme **trypsin** is the most commonly used reagent for specific proteolysis. Trypsin will only hydrolyze peptide bonds in which the carbonyl function is contributed by an arginine or a lysine residue. That is, trypsin cleaves on the C-side of Arg or Lys, generating a set of peptide fragments having Arg or Lys at their C-termini. The number of smaller peptides resulting from trypsin action is equal to the total number of Arg and Lys residues in the protein plus one—the protein's C-terminal peptide fragment (Figure 5.10).

Other proteases used in sequencing include **chymotrypsin**, which shows a strong preference for hydrolyzing peptide bonds formed by the carboxyl groups of the aromatic amino acids—phenylalanine, tyrosine, and tryptophan, and to a lesser extent, by leucine

Figure 5.10 Trypsin cleavage in protein sequencing. **(a)** Trypsin is a proteolytic enzyme, or *protease*, that specifically cleaves only those peptide bonds in which arginine or lysine contributes the carbonyl function. **(b)** The products of the reaction are a mixture of peptide fragments with C-terminal Arg or Lys residues *and* a single peptide derived from the polypeptide's C-terminal end.

Table 5.2 Specificity of Representative Polypeptide Cleavage Procedures Used in Sequence Analysis		
Method	Peptide Bond on Carboxyl (C) or Amino (N) Side of Susceptible Residue	Susceptible Residue(s)
<i>Proteolytic enzymes*</i>		
Trypsin	C	Arg and Lys
Chymotrypsin	C	Phe, Trp, and Tyr; Leu
Clostripain	C	Arg
Staphylococcal protease	C	Asp and Glu
Endopeptidase Lys-C	C	Lys
<i>Chemical methods</i>		
Cyanogen bromide	C	Met
NH ₂ OH	Asn-Gly bonds	
pH 2.5, 40°C	Asp-Pro bonds	

*Some proteolytic enzymes, including trypsin and chymotrypsin, will not cleave peptide bonds where proline is the amino acid contributing the N-atom.

(Table 5.2). Various other endopeptidases (proteases that, like trypsin and chymotrypsin, cleave peptide bonds within the interior of a polypeptide chain) are also used in sequence investigations. These include clostripain, which acts only at Arg residues; endopeptidase Lys-C, which cleaves only at Lys residues; and staphylococcal protease, which acts at the acidic residues, Asp and Glu. Because these endoproteases yield different sets of products, treatment of separate samples of a protein with different enzymes generates fragments whose sequences overlap. Resolution of the order of amino acid residues in the fragments yields the amino acid sequence in the original protein.

Chemical methods of proteolysis Several highly specific chemical methods of proteolysis are available, the most widely used being cyanogen bromide (CNBr) cleavage. CNBr acts upon methionine residues (Figure 5.11). The nucleophilic sulfur atom of Met reacts with CNBr, yielding a sulfonium ion that undergoes a rapid intramolecular rearrangement to form a cyclic iminolactone. Water readily hydrolyzes this iminolactone, cleaving the polypeptide and generating peptide fragments with C-terminal homoserine lactone residues at the former Met positions. A number of other chemical methods can also give specific fragmentation of polypeptides, including cleavage at asparagine–glycine bonds by hydroxylamine (NH₂OH) at pH 9 and selective hydrolysis at aspartyl–prolyl bonds under mildly acidic conditions. Table 5.2 summarizes the various procedures described here for polypeptide cleavage. These methods are only a partial list of the arsenal of reactions available to protein chemists. Cleavage products generated by these procedures must be isolated and individually sequenced to accumulate the information necessary to reconstruct the protein’s complete amino acid sequence. Sequencing of peptide fragments is still occasionally done by Edman degradation. However, far more often, intact proteins are fragmented and sequenced directly within mass spectrometers (see following discussion).

5.3g Step 6. Reconstruction of the Overall Amino Acid Sequence

The sequences obtained for the sets of fragments derived from two or more cleavage procedures are now compared, with the objective being to find overlaps that establish continuity of the overall amino acid sequence of the polypeptide chain. The strategy is illustrated by the example shown in Figure 5.12. Peptides generated from specific fragmentation of the polypeptide can be aligned to reveal the overall amino acid

OVERALL REACTION:

Figure 5.11 Cyanogen bromide (CNBr) is a highly selective reagent for cleavage of peptides only at methionine residues. (1) Nucleophilic attack of the Met S atom on the $-\text{C}\equiv\text{N}$ carbon atom, with displacement of Br. (2) Nucleophilic attack by the Met carbonyl oxygen atom on the R group. The cyclic derivative is unstable in aqueous solution. (3) Hydrolysis cleaves the Met peptide bond. C-terminal homoserine lactone residues occur where Met residues once were.

Figure 5.12 Summary of the sequence analysis of catrocollastatin-C, a 23.6 kDa protein found in the venom of the western diamondback rattlesnake *Crotalus atrox*. Sequences shown are given in the one-letter amino acid code. The overall amino acid sequence (216 amino acid residues long) for catrocollastatin-C as deduced from the overlapping sequences of peptide fragments is shown on the lines headed **CAT-C**. The other lines report the various sequences used to obtain the overlaps. These sequences were obtained from (a) **N-term**: Edman degradation of the intact protein in an automated Edman sequencer; (b) **M**: proteolytic fragments generated by CNBr cleavage, followed by Edman sequencing of the individual fragments (numbers denote fragments M1 through M5); (c) **K**: proteolytic fragments from endopeptidase Lys-C cleavage, followed by Edman sequencing (only fragments K3 through K6 are shown); (d) **E**: proteolytic fragments from *Staphylococcus* protease digestion of catrocollastatin sequenced in the Edman sequencer (only E13 through E15 are shown). (Adapted from Shimokawa, K., et al., 1997. Sequence and biological activity of catrocollastatin-C: A disintegrin-like/cysteine-rich two-domain protein from *Crotalus atrox* venom. *Archives of Biochemistry and Biophysics* **343**:35–43.)

sequence. Such comparisons are also useful in eliminating errors and validating the accuracy of the sequences determined for the individual fragments.

5.3h The Amino Acid Sequence of a Protein Can Be Determined by Mass Spectrometry

Mass spectrometry technology has evolved rapidly over the past decades and now dominates sequence determination as well as the new field of global protein study known as proteomics (Section 5.8). What follows here is a discussion of the basic principles of mass spectrometry, as applied to proteins.

Mass spectrometers exploit the difference in the mass-to-charge (m/z) ratio of ionized atoms or molecules to separate them from each other. The m/z ratio of a molecule is also a highly characteristic property that can be used to acquire chemical and structural information. Furthermore, molecules can be fragmented in distinctive ways in mass spectrometers, and the fragments that arise also provide quite specific structural information about the molecule. The basic operation of a mass spectrometer is to (1) evaporate and ionize molecules in a vacuum, creating gas-phase ions; (2) separate the ions in space and/or time based on their m/z ratios; and (3) measure the amount of ions with specific m/z ratios. Because proteins (as well as nucleic acids and carbohydrates) decompose upon heating rather than evaporating, methods to ionize such molecules for mass spectrometry (MS) analysis require innovative approaches. Two prominent MS modes for protein analysis are summarized in Table 5.3.

Figure 5.13 illustrates the basic features of electrospray mass spectrometry (ESI-MS). In this technique, the high voltage at the electrode causes proteins to pick up protons from the solvent, such that, on average, individual protein molecules acquire about one positive charge (proton) per kilodalton, leading to the spectrum of m/z ratios for a single protein species (Figure 5.14). Computer analysis can convert these data into a single spectrum that has a peak at the correct protein mass (Figure 5.14, inset).

Table 5.3 The Two Most Common Methods of Mass Spectrometry for Protein Analysis

Electrospray Ionization (ESI-MS)

A solution of macromolecules is sprayed in the form of fine droplets from a glass capillary under the influence of a strong electrical field. The droplets pick up positive charges as they exit the capillary; evaporation of the solvent leaves multiply charged molecules. The typical 20 kDa protein molecule will pick up 10 to 30 positive charges. The MS spectrum of this protein reveals all of the differently charged species as a series of sharp peaks whose consecutive m/z values differ by the charge and mass of a single proton (see Figure 5.14). Note that decreasing m/z values signify increasing number of charges per molecule, z . Tandem mass spectrometers downstream from the ESI source (ESI-MS/MS) can analyze complex protein mixtures (such as tryptic digests of proteins or chromatographically separated proteins emerging from a liquid chromatography column [LC/MS/MS]), selecting a single m/z species for collision-induced dissociation and acquisition of amino acid sequence information.

Matrix-Assisted Laser Desorption Ionization-Time of Flight (MALDI-TOF MS)

The protein sample is mixed with a chemical matrix that includes a light-absorbing substance excitable by a laser. A laser pulse is used to excite the chemical matrix, creating a microplasma that transfers the energy to protein molecules in the sample, ionizing them and ejecting them into the gas phase. Among the products are protein molecules that have picked up a single proton. These positively charged species can be selected by the MS for mass analysis. MALDI-TOF MS is very sensitive and very accurate.

Figure 5.13 The three principal steps in electrospray ionization mass spectrometry (ESI-MS). **(a)** Small, highly charged droplets are formed by electrostatic dispersion of a protein solution through a glass capillary subjected to a high electric field; **(b)** protein ions are desorbed from the droplets into the gas phase (assisted by evaporation of the droplets in a stream of hot N_2 gas); and **(c)** the protein ions are separated in a mass spectrometer and identified according to their m/z ratios. (Adapted from Figure 1 in Mann, M., and Wilm, M., 1995. Electrospray mass spectrometry for protein characterization. *Trends in Biochemical Sciences* 20:219–224.)

Figure 5.14 Electrospray ionization mass spectrum of the protein aerolysin K. The attachment of many protons per protein molecule (from fewer than 30 to more than 50 here) leads to a series of m/z peaks for this single protein. The equation describing each m/z peak is: $m/z = [M + n(\text{mass of proton})]/n(\text{charge on proton})$, where M = mass of the protein and n = number of positive charges per protein molecule. Thus, if the number of charges per protein molecule is known and m/z is known, M can be calculated. The inset shows a computer analysis of the data from this series of peaks that generates a single peak at the correct molecular mass of the protein. (Adapted from Figure 2 in Mann, M., and Wilm, M., 1995. Electrospray mass spectrometry for protein characterization. *Trends in Biochemical Sciences* 20:219–224.)

Sequencing by Tandem Mass Spectrometry Tandem MS (or MS/MS) allows sequencing of proteins by hooking two mass analyzers in tandem. The first is used as a filter to sort the oligopeptide fragments in a protein digest based on differences in their m/z ratios. Typically, the fragments are generated by trypsin digestion of the protein of interest. Such fragments are usually about 1 kD in mass and thus, pick up about one additional positive charge during ESI (in addition to the positive $-\text{NH}_3^+$ terminus). Each tryptic peptide selected by the first MS is directed toward the second mass analyzer; on the way, this peptide is fragmented by collision with inert gas molecules (a process called collision-induced dissociation, or CID), and the fragments are analyzed by the second MS (Figure 5.15). Fragmentation occurs primarily at the peptide bonds linking successive amino acids in the oligopeptide. Thus, the products include a series of fragments that represent a nested set of peptides differing in size by one amino acid residue. The various members of this set of fragments differ in mass by 56 atomic mass units [amu, the mass of the peptide backbone atoms ($\text{NH}-\text{CH}-\text{CO}$)] plus the mass of the R group at each position, which ranges from 1 amu (Gly) to 130 (Trp). Figure 5.16 illustrates MS/MS sequencing results obtained for a specific tryptic peptide.

MS sequencing has the advantages of very high sensitivity, fast sample processing, and the ability to work with mixtures of proteins. Sub-femtomole amounts (less than 10^{-12} moles) of peptide can be analyzed with these spectrometers. The protein need not be pure. Capillary HPLC-separated trypsin digests of protein mixtures can be directly loaded into the tandem MS spectrometer. Alternatively, separation of a complex mixture

Figure 5.15 Tandem mass spectrometry. (a) The basic configuration used in tandem MS. (b) Schematic description of tandem MS: Tandem MS involves electrospray ionization of a protein digest (IS in this figure), followed by selection of a single peptide ion mass for collision with inert gas molecules (He or N₂) and mass analysis of the fragment ions resulting from the collisions. (c) Fragmentation usually occurs at peptide bonds, as indicated. (Adapted from Yates, J. R., 1996. Protein structure analysis by mass spectrometry. *Methods in Enzymology* 271:351–376; and Gillece-Castro, B. L., and Stults, J. T., 1996. Peptide characterization by mass spectrometry. *Methods in Enzymology* 271:427–447.)

Example How do we know the sequence for the peptide in Figure 5.16 is –SPTDIEEGMR–COOH?

Step 1: Reading from left to right on the m/z axis, the first peak has an m/z of 175.11, the molecular mass of arginine- H^+ . This R represents the C-terminal amino acid in this tryptic peptide.

Step 2: The next peak, $m/z = 306.16$, is the peak of the tryptic peptide's C-terminal dipeptide, whose sequence can be represented as XR. The unknown amino acid, X, has a molecular mass of 306.16 minus 175.11, or 131.05, which is the molecular mass of a methionine residue, so the dipeptide sequence is MR.

Step 3: The next peak, $m/z = 363.17$, represents the C-terminal tripeptide XMR. X here has a molecular mass of 363.17 minus 306.16, or 57.01, the mass of a glycine residue, so the C-terminal tripeptide is GMR.

Step 4: The remaining amino acids in the sequence: Repeating this operation for the next seven peaks reveals the overall tryptic peptide sequence: –SPTDIEEGMR*

Figure 5.16 Mass spectrum of a selected tryptic peptide from a tandem MS (MS/MS) peptide sequencing experiment. The mass differences between the series yield the amino acid sequence, which is shown below the spectrum in reverse (C→N) from the conventional N→C direction. For example, 1134.58 minus 1047.43 equals 87.15; the mass of a serine residue; 1047.63 minus 950.38 equals 97.05, the mass of a proline residue. (Adapted from Figure 3c in Steen, H., and Mann, M., 2004. The abc's (and xyz's) of peptide sequencing. *Nature Reviews Molecular Cell Biology* 5:599–611.)

*Since the molecular masses of leucine (L) and isoleucine (I) are identical, there is uncertainty whether the sequence is SPTDIEEGMR or SPTDLEEGMR.

of proteins from a whole-cell extract by two-dimensional gel electrophoresis (see A Deeper Look box: Techniques Used in Protein Purification), followed by trypsin digestion of a specific protein spot on the gel and injection of the digest into the HPLC/tandem MS, gives information that can be used to identify the protein within sequence databases.

5.3i Sequence Databases Contain the Amino Acid Sequences of Millions of Different Proteins

The first protein sequence databases were compiled by protein chemists using chemical sequencing methods. Today, most protein sequence information has been derived from translating the nucleotide sequences of genes into codons and, thus, amino acid

sequences (see Chapter 30). Sequencing the order of nucleotides in cloned genes is a more rapid, efficient, and informative process than determining the amino acid sequences of proteins by chemical methods. Several electronic databases containing continuously updated sequence information are accessible by personal computer. Prominent among these is the SWISS-PROT protein sequence database on the ExPASy (Expert Protein Analysis System) Molecular Biology server and the PIR (Protein Identification Resource Protein Sequence Database) at <http://pir.georgetown.edu>. Mass spectrometric proteomics data are freely available from a number of repositories, including PRIDE (PRoteomics IDentification database) at <http://www.ebi.ac.uk/pride/>, PeptideAtlas at <http://peptideatlas.org>, and the Global Proteome Machine at <http://gpmdb.thegpm.org>. Further, protein information from genomic sequences is available in databases such as GenBank, accessible via the National Center for Biotechnology Information (NCBI) website located at <http://www.ncbi.nlm.nih.gov>. The protein sequence databases contain millions of entries.

In addition to sequence information, protein structural information can be found in the Worldwide Protein Data Bank (wwPDB), an ensemble of repositories composed of the Research Collaboratory for Structural Bioinformatics Protein Data Bank (RCSB PDB at <http://www.rcsb.org/pdb>), the Protein Data Bank Europe (PDBe), the Protein Data Bank Japan (PDBj), and the BioMagResBank (BMRB), which specifically houses NMR-derived structural information. The RCSB PDB site contains three-dimensional structural information on hundreds of thousands of proteins and nucleic acids.

5.4 | What Is the Nature of Amino Acid Sequences?

Figure 5.17 illustrates the relative frequencies of the amino acids in proteins. It is very unusual for a globular protein to have an amino acid composition that deviates substantially from these values. Apparently, these abundances reflect a distribution of amino acid polarities that is optimal for protein stability in an aqueous milieu. Membrane proteins tend to have relatively more hydrophobic and fewer ionic amino acids, a condition consistent with their location. Fibrous proteins may show compositions that are atypical with respect to these norms, indicating an underlying relationship between the composition and the structure of these proteins.

Proteins have unique amino acid sequences, and it is this uniqueness of sequence that ultimately gives each protein its own particular personality. Because the number of possible amino acid sequences in a protein is astronomically large, the probability that two proteins will, by chance, have similar amino acid sequences is negligible. Consequently, sequence similarities between proteins imply evolutionary relatedness.

Figure 5.17 Amino acid composition: frequencies of the various amino acids in proteins for all the proteins in the SWISS-PROT protein knowledge base. These data are derived from the amino acid composition of more than 600,000 different proteins. The range is from leucine at 9.66% to tryptophan at 1.09% of all residues.

5.4a Homologous Proteins from Different Organisms Have Homologous Amino Acid Sequences

Proteins sharing a significant degree of sequence similarity and structural resemblance are said to be **homologous**. Proteins that perform the same function in different organisms are also referred to as homologous. For example, the oxygen transport protein hemoglobin serves a similar role and has a similar structure in all vertebrates. The study of the amino acid sequences of homologous proteins from different organisms provides very strong evidence for their evolutionary origin within a common ancestor. Homologous proteins characteristically have polypeptide chains that are nearly identical in length, and the degree to which their sequences share identity provides a direct measure of the evolutionary relationship between the species from which they are derived.

Homologous proteins can be further subdivided into **orthologous** and **paralogous** proteins. Orthologous proteins are proteins from different species that have homologous amino acid sequences (and often a similar function). Orthologous proteins arose from a common ancestral gene during evolution. Paralogous proteins are proteins found within a single species that have homologous amino acid sequences; paralogous proteins arose through gene duplication. For example, the α - and β -globin chains of hemoglobin are paralogs.

5.4b Computer Programs Can Align Sequences and Discover Homology between Proteins

How is homology revealed? Protein and nucleic acid sequence databases (see Section 5.3) provide enormous resources for sequence comparisons. If two proteins share homology, it can be revealed through alignment of their sequences using powerful computer programs. In such studies, a given amino acid sequence is used to query the databases for proteins with similar sequences. **BLAST** (**B**asic **L**ocal **A**lignment **S**earch **T**ool) is one commonly used program for rapid searching of sequence databases. The BLAST program detects local as well as global alignments where sequences are in close agreement. Even regions of similarity shared between otherwise unrelated proteins can be detected. Discovery of sequence similarities between proteins can be an important clue to the function of uncharacterized proteins. Similarities are also useful in assigning related proteins to protein families.

The process of sequence alignment is an operation akin to sliding one sequence along another in a search for regions where the two sequences show a good match. Positive scores are assigned everywhere the amino acid in one sequence is similar to or identical with the amino acid in the other; the greater the overall score, the better the match between the two protein sequences. Sometimes two sequences match well at several places along their lengths, but, in one of the proteins, the matching segments are interrupted by a sequence that is dissimilar. When such an interruption is found by the computer program, it inserts a **gap** in the uninterrupted sequence to bring the matching segments of the two sequences into better alignment (Figure 5.18). Because any two sequences would show similarity if a sufficient number of gaps were introduced, a **gap penalty** is imposed for each gap. Gap penalties are negative numbers that lower the overall similarity score. Gaps arise naturally during evolution through insertion and deletion mutations, so-called **indels**, which add or remove residues in the gene and, consequently, the protein. The optimal sequence alignment between two proteins is one that maximizes sequence alignments while minimizing gaps.

Methods for alignment and comparison of protein sequences depend upon some quantitative measure of how similar any two sequences are. One way to measure similarity is to use a matrix that assigns scores for all possible substitutions of one amino acid for another. BLOSUM62 is the substitution matrix most often used with BLAST. This matrix assigns a probability score for each position in an alignment based on the frequency with which that substitution occurs in the consensus sequences of related proteins. **BLOSUM** is an acronym for **B**locks **S**ubstitution **M**atrix, a matrix that scores each position on the basis of observed frequencies of different amino acid substitutions within blocks of local

Figure 5.18 Alignment of the amino acid sequences of two protein homologs using gaps. Shown are parts of the amino acid sequences of the catalytic subunits from the major ATP-synthesizing enzyme (ATP synthase) in a representative archaea (*Sulfolobus acidocaldarius*) and a bacterium (*Escherichia coli*). These protein segments encompass the nucleotide-binding site of these enzymes. Identical residues in the two sequences are shown in red. Introduction of a three-residue-long gap in the archaeal sequence optimizes alignment of the two sequences.

Figure 5.19 The BLOSUM62 substitution matrix provides scores for all possible exchanges of one amino acid with another. (From Henikoff, S., and Henikoff, J. G., 1992. Amino acid substitution matrices from protein blocks. *Proceedings of the National Academy of Sciences, USA* **89**:10915–10919.)

alignments in related proteins. In the BLOSUM62 matrix, the scores are derived using sequences sharing no more than 62% identity (Figure 5.19). BLOSUM substitution scores range from -4 (lowest probability of substitution) to 11 (highest probability of substitution). For example, to look up the value corresponding to the substitution of an asparagine (N) by a tryptophan (W), or vice versa, find the intersection of the “N” column with the “W” row in Figure 5.19. The value -4 means that the substitution of N for W, or vice versa, is not very likely. On the other hand, the substitution of V for I (BLOSUM score: 3), or vice versa, is very likely. Amino acids whose side chains have unique qualities (such as C, H, P, or W) have high BLOSUM62 scores because replacing them with any other amino acid may change the protein significantly. Amino acids that are similar (such as R and K; or D and E; or A, V, L, and I) have low scores, since one can replace the other with less likelihood of serious change to the protein structure.

Cytochrome *c* as an Example of Orthology The electron transport protein **cytochrome *c***, found in the mitochondria of all eukaryotic organisms, provides a well-studied example. Amino acid sequencing of cytochrome *c* from more than 40 different species has revealed that there are 28 positions in the polypeptide chain where the same amino acid residues are always found (Figure 5.20). These **invariant residues** serve roles crucial

to the biological function of this protein, and thus substitutions of other amino acids at these positions cannot be tolerated. The number of amino acid differences between two cytochrome *c* sequences is proportional to the phylogenetic difference between the species from which they are derived. Cytochrome *c* in humans and in chimpanzees is identical; human and another mammalian (sheep) cytochrome *c* differ at 10 residues. The human cytochrome *c* sequence has 14 variant residues from a reptile sequence (rattlesnake), 18 from a fish (carp), 29 from a mollusc (snail), 31 from an insect (moth), and more than 40 from yeast or higher plants (cauliflower).

The Phylogenetic Tree for Cytochrome *c* Figure 5.21 displays a **phylogenetic tree** (a diagram illustrating the evolutionary relationships among a group of organisms) constructed from the sequences of cytochrome *c*. The tips of the branches are occupied by contemporary species whose sequences have been determined. The tree has been deduced by computer analysis of these sequences to find the minimum number of mutational changes connecting the branches. Other computer methods can be used to infer potential ancestral sequences represented by *nodes*, or branch points, in the tree. Such analysis ultimately suggests a primordial cytochrome *c* sequence lying at the base of the tree. Evolutionary trees constructed in this manner, that is, solely on the basis of amino acid differences occurring in the primary structure of one selected protein, show remarkable agreement with phylogenetic relationships derived from more classic approaches and have given rise to the field of *molecular evolution*.

Figure 5.21 This phylogenetic tree depicts the evolutionary relationships among organisms as determined by the similarity of their cytochrome *c* amino acid sequences. The numbers along the branches give the amino acid changes between a species and a hypothetical progenitor. Note that extant species are located only at the tips of branches. (Adapted from Creighton, T. E., 1983. *Proteins: Structure and Molecular Properties*. San Francisco: W. H. Freeman.)

Figure 5.20 The sequence of cytochrome *c* from more than 40 different species reveals that 28 residues are invariant. These invariant residues are scattered irregularly along the polypeptide chain, except for a cluster between residues 70 and 80. All cytochrome *c* polypeptide chains have a cysteine residue at position 17, and all but one have another Cys at position 14. These Cys residues serve to link the heme prosthetic group of cytochrome *c* to the protein.

5.4c Related Proteins Share a Common Evolutionary Origin

Amino acid sequence analysis reveals that proteins with related functions often show a high degree of sequence similarity. Such findings suggest a common ancestry for these proteins.

Oxygen-Binding Heme Proteins Myoglobin and the α - and β -globin chains of hemoglobin constitute a set of **paralogous proteins**. **Myoglobin**, the oxygen-binding heme protein of muscle, consists of a single polypeptide chain of 153 residues. **Hemoglobin**, the oxygen transport protein of erythrocytes, is a tetramer composed of two **α -chains** (141 residues each) and two **β -chains** (146 residues each). These globin paralogs—myoglobin, α -globin, and β -globin—share a strong degree of sequence and structural homology (Figure 5.22). Human myoglobin and the human α -globin chain show 38 amino acid identities, whereas human α -globin and human β -globin have 64 residues in common. The relatedness suggests an evolutionary sequence of events in which chance mutations led to amino acid substitutions and divergence in primary structure. The ancestral myoglobin gene diverged first, after duplication of a primordial globin gene had given rise to its progenitor and an ancestral hemoglobin gene (Figure 5.23). Subsequently, the ancestral hemoglobin gene duplicated to generate the progenitors of

Figure 5.22 The structures of the globin chains of human hemoglobin and myoglobin show a strong degree of homology. The amino acid sequences of α - and β -globin chains share 64 residues of their approximately 140 residues in common. Myoglobin and the α -globin chain have 38 amino acid sequence identities. This homology is further reflected in these proteins' tertiary structure.

the present-day α -globin and β -globin genes. The ability to bind O_2 via a heme prosthetic group is retained by all three of these polypeptides.

Serine Proteases Whereas the globins provide an example of gene duplication giving rise to a set of proteins in which the biological function has been highly conserved, other sets of proteins united by strong sequence homology show variation in their properties. **Trypsin**, **chymotrypsin**, and **elastase** are members of a class of proteolytic enzymes called **serine proteases** because of the central role played by specific serine residues in their catalytic activity. **Thrombin**, an essential enzyme in blood clotting, is also a serine protease. These enzymes show sufficient sequence homology to conclude that they arose via duplication of a progenitor serine protease gene, even though their substrate preferences are now quite different.

5.4d Apparently Different Proteins May Share a Common Ancestry

A more remarkable example of evolutionary relatedness is inferred from sequence homology between hen egg white **lysozyme** and human milk **α -lactalbumin**, proteins that have different biological activity. Lysozyme (129 residues) and α -lactalbumin (123 residues) are identical at 48 positions. Lysozyme hydrolyzes the polysaccharide wall of bacterial cells, whereas α -lactalbumin regulates milk sugar (lactose) synthesis in the mammary gland. Although both proteins act in reactions involving carbohydrates, their functions show little similarity otherwise. Nevertheless, their tertiary structures are strikingly similar (Figure 5.24). It is conceivable that many proteins are related in this way, but time and the course of evolutionary change erased most evidence of their common ancestry.

5.4e A Mutant Protein Is a Protein with a Slightly Different Amino Acid Sequence

In a large population of individuals, a considerable number of sequence variants can be found for a protein. These variants are a consequence of **mutations** in a gene (alterations in DNA nucleotide sequence) that have arisen naturally within the population. Gene mutations lead to mutant forms of the protein in which the amino acid sequence is altered at one or more positions. Many of these mutant forms are “neutral” in that the functional properties of the protein are unaffected by the amino acid substitution. Others may be nonfunctional (if loss of function is not lethal to the individual), and still others may display a range of aberrations between these two extremes. The severity of the effects on function depends on the nature of the amino acid substitution and its role in the protein. These conclusions are exemplified by the hundreds of human hemoglobin variants that have been discovered.

A variety of effects on the hemoglobin molecule are seen in these mutants, including alterations in oxygen affinity, heme affinity, stability, solubility, and subunit interactions between the α -globin and β -globin polypeptide chains. Some variants show no apparent changes, whereas others, such as HbS, sickle-cell hemoglobin, result in serious illness. Sickle cell anemia is due to the substitution of the glutamate residue at position 6 in the β -globin amino acid sequence with a valine residue (E^6V). This diversity of response indicates that some amino acid changes are relatively unimportant, whereas others drastically alter one or more functions of a protein.

Figure 5.24 The tertiary structures of hen egg white lysozyme and human α -lactalbumin are very similar.

5.5 | How Are Polypeptides Synthesized in the Laboratory?

Chemical synthesis of peptides and polypeptides of defined sequence can be carried out in the laboratory. Chemical synthesis allows scientists to create polypeptides of any desired sequence, an advantage in testing ideas regarding relationships between protein structure and function. Formation of peptide bonds linking amino acids

together is not a chemically complex process, but making a specific peptide can be challenging because various functional groups present on side chains of amino acids may also react under the conditions used to form peptide bonds. Furthermore, if correct sequences are to be synthesized, the α -COOH group of residue x must be linked to the α -NH₂ group of neighboring residue y in a way that prevents reaction of the amino group of x with the carboxyl group of y . In essence, any functional groups to be protected from reaction must be blocked while the desired coupling reactions proceed. Also, the blocking groups must be removable later under conditions in which the newly formed peptide bonds are stable.

5.5a Orthogonal Synthesis of Peptides

An ingenious synthetic strategy to circumvent these technical problems is *orthogonal synthesis*. An orthogonal system is defined as a set of distinctly different blocking groups—one for side-chain protection, another for α -amino protection, and a third for α -carboxyl protection or anchoring to a solid support (see following discussion). Ideally, any of the three classes of protecting groups can be removed in any order and in the presence of the other two, because the reaction chemistries of the three classes are sufficiently different from one another. In peptide synthesis, all reactions must proceed with high yield if peptide recoveries are to be acceptable. Peptide formation between amino and carboxyl groups is not spontaneous under normal conditions (see Chapter 4), so one or the other of these groups must be activated to facilitate the reaction. Despite these difficulties, biologically active peptides and polypeptides have been re-created by synthetic organic chemistry. Milestones include the pioneering synthesis of the nonapeptide posterior pituitary hormones oxytocin and vasopressin by Vincent du Vigneaud in 1953 and, in later years, larger proteins such as insulin (21 A-chain and 30 B-chain residues), ribonuclease A (124 residues), and HIV protease (99 residues).

5.5b Solid-Phase Methods Are Very Useful in Peptide Synthesis

Bruce Merrifield and his collaborators pioneered a clever solution to the problem of recovering intermediate products in the course of a synthesis. The carboxyl-terminal residues of synthesized peptide chains are covalently anchored to an insoluble resin (polystyrene particles) that can be removed from reaction mixtures simply by filtration. After each new residue is added successively at the free amino-terminus, the elongated product is recovered by filtration and readied for the next synthetic step. Because the growing peptide chain is coupled to an insoluble resin bead, the method is called **solid-phase synthesis**. The procedure is detailed in Figure 5.25. This cyclic process is automated and computer controlled so that the reactions take place in a small cup with reagents being pumped in and removed as programmed.

5.6 | Do Proteins Have Chemical Groups Other Than Amino Acids?

Many proteins consist of only amino acids and contain no other chemical groups. The enzyme ribonuclease and the contractile protein actin are two such examples. Such proteins are called **simple proteins**. However, many other proteins contain various chemical constituents as an integral part of their structure. Some of these constituents arise through covalent modification of amino acid side chains in proteins after the protein has been synthesized. Such alterations are called **post-translational modifications**. For example, the reaction of two cysteine residues in a protein to form a disulfide linkage (Figure 4.8b) is a post-translational modification. Many of the prominent post-translational modifications, such as those listed in Table 5.4, can act as “on–off switches” that regulate the function or cellular location of the protein. Over 600 post-translational modifications are listed in the RESID database accessible through the Georgetown University Protein Information Resource at <http://pir.georgetown.edu/resid/resid.shtml>.

Figure 5.25 Solid-phase synthesis of a peptide. The 9-fluorenylmethoxycarbonyl (Fmoc) group is an excellent orthogonal blocking group for the α -amino group of amino acids during organic synthesis because it is readily removed under basic conditions that don't affect the linkage between the insoluble resin and the α -carboxyl group of the growing peptide chain. (inset) *N,N'*-diisopropylcarbodiimide (DIPCDI) is one agent of choice for activating carboxyl groups to condense with amino groups to form peptide bonds. (1) The carboxyl group of the first amino acid (the carboxyl-terminal amino acid of the peptide to be synthesized) is chemically attached to an insoluble resin particle (the *aminoacyl-resin particle*). (2) The second amino acid, with its amino group blocked by a Fmoc group and its carboxyl group activated with DIPCDI, is reacted with the aminoacyl-resin particle to form a peptide linkage, with elimination of DIPCDI as diisopropylurea. (3) Then, basic treatment (with piperidine) removes the N-terminal Fmoc blocking group, exposing the N-terminus of the dipeptide for another cycle of amino acid addition. (4) Any reactive side chains on amino acids are blocked by addition of acid-labile *tertiary* butyl (*t*Bu) groups as orthogonal protective functions. (5) After each step, the peptide product is recovered by collection of the insoluble resin beads by filtration or centrifugation. Following cyclic additions of amino acids, the completed peptide chain is hydrolyzed from linkage to the insoluble resin by treatment with HF; HF also removes any *t*Bu protecting groups from side chains on the peptide.

Table 5.4 Some Prominent Post-Translational Modifications Found in Proteins			
Name	Nonprotein Part	Amino Acid Side Chain Modified	Examples
Phosphorylation	–PO ₃ ^{2–}	S, T, Y	Hormone receptors, regulatory enzymes
Acetylation	–CH ₂ COO [–]	K	Histones, metabolic enzymes
Methylation	–CH ₃	K, R	Histones
Acylation	Palmitic acid	C	G-protein-coupled receptors
Prenylation	Prenyl group	C	Ras p21
ADP-ribosylation	ADP-ribose	H, R	G proteins, eukaryotic elongation factors
Adenylation	AMP	Y	Glutamine synthetase

Table 5.5 Some Common Conjugated Proteins			
Name	Nonprotein Part	Association	Examples
Lipoproteins	Lipids	Covalent or noncovalent	Blood lipoprotein complexes (HDL, LDL)
Nucleoproteins	RNA, DNA	Noncovalent	Ribosomes, chromosomes
Glycoproteins	Carbohydrate groups	Covalent	Immunoglobulins, LDL receptor
Metalloproteins and metal-activated proteins	Ca ²⁺ , K ⁺ , Fe ²⁺ , Zn ²⁺ , Co ²⁺ , others	Covalent or noncovalent	Metabolic enzymes, kinases, phosphatases, among others
Hemoproteins	Heme group	Covalent or noncovalent	Hemoglobin, cytochromes
Flavoproteins	FMN, FAD	Covalent or noncovalent	Electron transfer enzymes

The general term for proteins containing nonprotein constituents is **conjugated proteins** (Table 5.5). Because association of the protein with the conjugated group does not occur until the protein has been synthesized, these associations are post-translational as well, although such terminology is usually not applied to these proteins (with the possible exception of glycoproteins). As Table 5.5 indicates, conjugated proteins are typically classified according to the chemistry of the nonprotein part. If the nonprotein part participates in the protein’s function, it is referred to as a **prosthetic group**. Conjugation of proteins with these different nonprotein constituents dramatically enhances the repertoire of functionalities available to proteins.

A common form of post-translational modification not to be found in such a database or in Table 5.4 is the removal of amino acids from the protein by proteolytic cleavage. Many proteins localized in specific subcellular compartments have N-terminal **signal sequences** that stipulate their proper destination, much like zipcodes specify postal regions. Such signal sequences typically are clipped off during their journey. Other proteins, such as some hormones or potentially destructive proteases, are synthesized in an inactive form and converted into an active form through proteolytic removal of some of their amino acids.

5.7 | What Are the Many Biological Functions of Proteins?

Proteins are the agents of biological function. Virtually every cellular activity is dependent on one or more particular proteins. Thus, a convenient way to classify the enormous number of proteins is to group them according to the biological roles they serve.

5.7a Proteins Are the Agents of Biological Function

Proteins fill essentially every biological role, with the exception of information storage. The ability to bind other molecules (ligands) is common to many proteins. Binding proteins typically interact noncovalently with their specific ligands. Transport proteins are one class of binding proteins. Transport proteins include membrane proteins that transport substances across membranes as well as soluble proteins that deliver specific nutrients or waste products throughout the body. Scaffold proteins are a class of binding proteins that uses protein–protein interactions to recruit other proteins into multimeric assemblies. Such assemblies coordinate the flow of information in cells. Catalytic proteins (enzymes) mediate almost every metabolic reaction. Regulatory proteins that bind to specific nucleotide sequences within DNA control gene expression. Hormones are another kind of regulatory protein; they convey information about the environment and deliver this information to cells when they bind to specific receptors. Switch proteins such as G-proteins can switch between two conformational states—an “on” state and an “off” state—and act via this conformational switching as regulatory proteins. Structural proteins give form to cells and subcellular structures. The great diversity in function that characterizes biological systems is based on attributes that proteins possess.

The human genome contains slightly more than 19,000 protein-encoding genes and the proteins they encode can be grouped according to biological function. The three categories with the most entries are enzymes, nucleic acid-binding proteins, and proteins involved in signal transduction, but more than a dozen other categories can be considered, including transport proteins, structural proteins, and motor proteins. Remarkably, the biological function remains unknown for some 15% or so of the proteins encoded by the human genome.

5.7b All Proteins Function through Specific Recognition and Binding of Some Target Molecule

Although the classification of proteins according to function has advantages, many proteins are not assigned readily to one of the traditional groupings. Further, classification can be somewhat arbitrary, because many proteins fit more than one category. However, for all categories, the protein always functions through specific recognition and binding of some other molecule, although for structural proteins, it is usually self-recognition and assembly into stable multimeric arrays. Protein behavior provides the cardinal example of *molecular recognition through structural complementarity*, a fundamental principle of biochemistry that was presented in Chapter 1.

Protein Binding Protein–ligand interactions may be weak or they may be so strong that it is very difficult to dislodge the ligand from the protein. The interaction of a protein with its target often can be described in simple quantitative terms. Let’s explore the simplest situation in which a protein has a single binding site for the molecule it binds (its **ligand**; Chapter 1). If we treat the interaction between the protein (P) and the ligand (L) as a dissociation reaction:

The equilibrium constant for the reaction as written

$$K_{\text{eq}} = [P][L]/[PL]$$

is a **dissociation constant**, because it describes the dissociation of the ligand from the protein. Biochemists typically use dissociation constants (K_D) to describe binding phenomena. Because brackets ([]) denote molar concentrations, dissociation constants have the units of M .

Figure 5.26 Saturation curve or binding isotherm.

Typically, the ligand concentration is much greater than the protein concentration. Under such conditions, a plot of the moles of ligand bound per mole of protein (defined as $[PL]/([P] + [PL])$) versus $[L]$ yields a hyperbolic curve known as a **saturation curve** or **binding isotherm** (Figure 5.26).

If we define the fractional saturation of P with L, $[PL]/([P] + [PL])$, as ν , a little algebra yields

$$\nu = [L]/(K_D + [L])$$

Thus, when $\nu = 0.5$,

$$[L] = K_D$$

That is, the concentration of L where half the protein has L bound is equal to the value of K_D . The smaller this number is, the better the ligand binds to the protein; that is, a small K_D means that the protein is half-saturated with L at a low concentration of L. In other words, if K_D is small, the protein binds the ligand avidly. Typical K_D values fall in a range from $10^{-3} M$ to $10^{-15} M$. As a rule of thumb, K_D values greater than $10^{-4} M$ indicate weak protein:ligand affinity, $10^{-7} M$ —average affinity, and less than $10^{-9} M$ —high affinity.

The Ligand-Binding Site Ligand binding occurs through noncovalent interactions between the protein and ligand. The lack of covalent interactions means that binding is readily reversible. Proteins display specificity in ligand binding because they possess a specific site, the **binding site**, within their structure that is complementary to the structure of the ligand, its charge distribution, and any H-bond donors or acceptors it might have. Structural complementarity within the binding site is achieved because part of the three-dimensional structure of the protein provides an ensemble of amino acid side chains (and polypeptide backbone atoms) that establish an interactive cavity complementary to the ligand molecule. When a ligand binds to the protein, the protein usually undergoes a conformational change. This new protein conformation provides an even better fit with the ligand than before. Such changes are called **ligand-induced conformational changes**, and the result is an even more stable interaction between the protein and its ligand.

Thus, in a general sense, most proteins are binding proteins because ligand binding is a hallmark of protein function. Catalytic proteins (enzymes) bind substrates; regulatory proteins bind hormones or other proteins or regulatory sequences in genes; structural proteins bind to and interact with each other; and the many types of transport proteins

bind ligands, facilitating their movement from one place to another. Many proteins accomplish their function through the binding of other protein molecules, a phenomenon called **protein–protein interaction**. Some proteins engage in protein–protein interactions with proteins that are similar or identical to themselves so that an oligomeric structure is formed, as in hemoglobin. Other proteins engage in protein–protein interactions with proteins that are very different from themselves, as in the anchoring proteins or the scaffolding proteins of signaling pathways.

5.8 | What Is the Proteome and What Does It Tell Us?

The essential questions in cellular biology and biochemistry are: What is the cell doing, and why is it doing it? The full genetic potential of a cell (what it is capable of doing) is contained within its genome, but not all genes are expressed at any moment in time. Those genes that are being expressed are defined by the transcriptome, but what the cell is doing is not directly determined by the transcriptome. A more accurate reflection of what a cell is doing at any moment in time is found in the proteome because proteins are the agents of cellular function. Further, the proteome is much more complex than the genome. Whereas there are only 20,000 or so protein-coding genes in the human genome, estimates suggest that there are hundreds of thousands of different proteins, perhaps even a million or more. This discrepancy exists because one gene may give rise to a large number of protein products through a range of processes, such as post-translational modification or alternative RNA splicing or RNA editing.

5.8a The Proteome Is Large and Dynamic

Proteins are synthesized, processed, delivered to appropriate subcellular compartments, assembled into complexes, and degraded. Different cells have different sets of proteins. The same cell has different proteins at different times. The lifetimes of different proteins vary from minutes to years. Defining the proteome requires techniques that can unambiguously identify each protein and determine how much of it is present. Bacterial cells contain about 2 million protein molecules per 10^{-15} L (approximately the volume of an *E. coli* cell). Indeed, cells from bacteria to yeast to mammals seem to be rather uniform in containing 2 to 4 million protein molecules per 10^{-15} L. A liver cell is about 8000 times larger than an *E. coli* cell, so it would contain as many as 30 billion protein molecules. These numbers reflect total number of proteins/cell. In actuality, in human cells, the number of molecules of each protein can vary from as low as 10 or so copies per cell to as much as 100 billion, by some estimates. Thus, the concentrations of different proteins in a human cell can vary over ten orders of magnitude. Clearly, proteomics poses a daunting analytical challenge. The tools of proteomics are global purification strategies to separate complex mixtures, followed by sequence determination using mass spectroscopy to both identify and quantify each of the different proteins present.

5.8b Determining the Proteome of a Cell

Proteomics seeks to describe the full complement of proteins present in a specific cell type under a defined set of conditions. In a typical experimental approach to this problem, proteins from a cellular extract are first separated by two independent chromatographic methods within a single chromatographic column (Figure 5.27). The upper part of the column contains an ion exchange resin that separates proteins based on their charge, and the lower part contains a reverse phase separation material that separates proteins on the basis of their solubility. As the separated proteins emerge from the column, they are led into an ESI mass spectrometer that identifies them by mass and provides information regarding their abundance. The MS data can then be

Figure 5.27 In a typical proteomics study, proteins obtained from a cell extract are cleaved into peptides by proteases, the proteolytic fragments are separated by HPLC using two different chromatographic media (such as ion exchange and reversed-phase), and the resolved fragments are analyzed by mass spectrometry (LC/MS/MS). The sequences of individual, cleaved peptides from two different proteolytic digestions provide the overlaps necessary to construct the sequence of each protein in the original extract. This reconstruction is performed by computer algorithms. The complete protein sequence of every protein in the original extract is then used to identify the protein within a proteomic or genomic database.

Critical Developments in Biochemistry

Two New Suffixes in Molecular Biology and Biochemistry: “-ome” and “-omics”

The emergence of technologies to identify *all* of the molecules or functions of a particular class within a given cell or organism is exemplified by the Human Genome Project (1991 to 2003). This project revealed the identity of all of the human genes (see the Human Biochemistry box: The Human Genome Project in Chapter 11). The suffix “-ome” is now applied to the entire set of a particular class of molecules, in terms such as “**transcriptome**” (all the RNA transcripts of genes in a cell at a particular moment in time), “**lipidome**” (all the lipids in a cell at a given moment), “**glycome**” (all the carbohydrates), or the one that interests us here, the “**proteome**” (all of the proteins present in a cell or organism under defined conditions at a specified time).

Methodologies aimed at identifying and characterizing the global set of a particular class of molecules or functions led to

the establishment of new fields of science, such as genomics—the study of all of the genes in a particular cell, organism, or group of organisms—or **proteomics**—the scientific field devoted to the study of all of the proteins in a cell or organism, usually under a specified set of conditions of growth. These fields rely on large-scale, comprehensive determination of which molecules of a particular class are present and how much of each. Comparative -omic studies reveal more information, often of medical relevance, such as a comparison of all of the proteins in a liver cell versus all of the proteins in a hepatoma cell (a cancerous liver cell).

Thus, “-ome” defines the ensemble of molecules and “-omics” refers to the field that studies them.

analyzed by comparison with known protein databases to reveal the identity and amount of every protein in the cellular extract, and thus, in the cells of interest. Proteomics databases are found in the PRIDE Archive <http://www.ebi.ac.uk/pride/larchivel> that arranges entries by species, MAPU 2.0, the Max Planck Institute Unified Proteome Database <http://www.mapuproteome.com/> that includes bodily fluid and organelle proteomes, and the human proteome database at Proteomics DB <https://www.proteomicsdb.org/>, among others.

A Deeper Look

The Human Proteome Project and the Human Protein Atlas

Initiated in 2010, the Human Proteome Project (HPP) serves as an international framework for global collaboration and data sharing in order to define the complete human genome encoded proteome (see <https://lhupo.org>). The HPP counts 19,773 protein-coding genes in the human genome and as of 2020, has documented mass spectroscopic evidence of proteins produced by 17,874 of these genes. It is estimated that only 10,000 or so genes are expressed in any particular human cell at any time, so the proteome of a cell never reflects the complete genome. On the other hand, since proteins can exist in multiple forms as a result of post-translational modifications, the scale of the proteome is much greater than the scale of the genome. The work of the HPP is significant to health and medicine. While the human genome specifies the full range

of human biology, the proteome is a dynamic report on what a particular cell type or tissue might be doing at a particular moment in time.

The Europe-based Human Protein Atlas is a similar project and is aimed at mapping all the proteins in cells, tissues, and organs under normal as well as pathological states. Launched in 2003, it relies on an integrated transcriptomics and proteomics approach. In 2020, version 20 of the Human Protein Atlas was announced. It includes a number of sub-atlases: the Single Cell Type Atlas, the Tissue Atlas, the Pathology Atlas, the Blood Atlas, the Brain Atlas, and the Cell Atlas, each of which is a compendium of the proteins expressed within the stated category. See the online resource Human Protein Atlas portal at www.proteinatlas.org.

Foundational Biochemistry Things You Should Know after Reading Chapter 5.

- Proteins fall into three general classes on the basis of shape and solubility: fibrous, globular, and membrane.
- Protein structure is described in terms of four levels of organization:
 - primary (1°)—amino acid sequence
 - secondary (2°)—patterns arising by hydrogen bonding
 - tertiary (3°)—folding of the polypeptide chain
 - quaternary (4°)—subunit organization
- Noncovalent forces underlie the higher (2°, 3°, 4°) levels of protein structure.
- The overall three-dimensional structure of a protein is called its conformation.
- Proteins can be purified from cellular sources by exploiting their size, charge, and affinity differences.
- The amino acid compositions of proteins differ, but soluble proteins tend to have about one-third charged amino acid residues, one-third hydrophobic, and one-third polar but uncharged.
- The amino acid sequence of a protein is the defining characteristic of a protein.
- Chemical and enzymatic methodologies can be used to determine the sequence of amino acids along a polypeptide chain.
- The amino acid sequence of a protein is more often determined by mass spectrometric analysis.
- Most of the available amino acid sequence information for proteins was obtained from nucleotide sequence analysis of genes and genomes.
- Homologous proteins share sequence similarity and structural resemblance and often perform similar functions across different organisms.
- Homologous proteins can be subclassified as orthologous or paralogous:
 - Orthologous proteins are proteins that perform the same function in different cells.
 - Paralogous proteins are proteins found within the same species that have homologous amino acid sequences; paralogous proteins arise through gene duplication.
- Related proteins shared a common evolutionary origin.
- A mutant protein is a protein with a slightly different amino acid sequence.
- Polypeptides of defined sequences can be chemically synthesized; the most effective strategy for chemical synthesis relies on solid-phase methods.
- Post-translational modification of proteins can introduce new properties into proteins.
- Proteins may have other chemical groups attached to them, such as carbohydrates to form glycoproteins.
- Proteins are the agents of biological function.
- All proteins function through recognition and binding of some target molecule.
- The proteome is the entire set of different proteins found in a particular cell at a specific moment in time.
- Proteomics is the science of describing the proteome.
- The tools of proteomics are protein separation, followed by identification, usually by mass spectrometry.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. Determining the Subunit Organization of a Protein From Its Molecular Weight and Metal Content** The element molybdenum (atomic weight 95.95) constitutes 0.08% of the weight of nitrate reductase. If the molecular weight of nitrate reductase is 240,000, what is its likely quaternary structure?

- 2. Solving the Sequence of an Oligopeptide from Sequence Analysis Data** Amino acid analysis of an oligopeptide seven residues long gave

Asp Leu Lys Met Phe Tyr

The following facts were observed:

- Trypsin treatment had no apparent effect.
- The phenylthiohydantoin released by Edman degradation was

- Brief chymotrypsin treatment yielded several products, including a dipeptide and a tetrapeptide. The amino acid composition of the tetrapeptide was Leu, Lys, and Met.
- Cyanogen bromide treatment yielded a dipeptide, a tetrapeptide, and free Lys.

What is the amino acid sequence of this heptapeptide?

- 3. Solving the Sequence of an Oligopeptide from Sequence Analysis Data** Amino acid analysis of a decapeptide revealed the presence of the following products:

NH ₄ ⁺	Asp	Glu	Tyr	Arg
Met	Pro	Lys	Ser	Phe

The following facts were observed:

- Neither carboxypeptidase A nor B treatment of the decapeptide had any effect.
- Trypsin treatment yielded two tetrapeptides and free Lys.
- Clostripain treatment yielded a tetrapeptide and a hexapeptide.
- Cyanogen bromide treatment yielded an octapeptide and a dipeptide of sequence NP (using the one-letter codes).
- Chymotrypsin treatment yielded two tripeptides and a tetrapeptide. The N-terminal chymotryptic peptide had a net charge of -1 at neutral pH and a net charge of -3 at pH 12.
- One cycle of Edman degradation gave the PTH derivative

What is the amino acid sequence of this decapeptide?

- 4. Getting Insights into a Protein's Properties from Its Behavior during Purification** A protein mixture consisting of proteins A, B, and C was subjected to various protein purification steps. First, the protein mixture was applied to an ion exchange column having anionic groups. When the column was washed with an increasing concentration gradient of chloride ions, the order of elution of the three proteins was B, then C, and finally, A. Next, the protein mixture was chromatographed on a gel filtration column. The order of elution of the three proteins from this column was C, A, B. Finally, the protein

mixture was passed over a chromatography column containing a flavin affinity matrix. Only protein A was retained by the column. What can you infer about the relative properties of proteins A, B, and C?

- 5. N-Terminal Analysis** A protein was purified and confirmed to consist of only a single molecule with a single molecular mass. Yet N-terminal analyses resulted in the identification of two different amino acids. Give a possible explanation.

- 6. Solving the Sequence of an Oligopeptide from Sequence Analysis Data** Amino acid analysis of an octapeptide revealed the following composition:

2 Arg 1 Gly 1 Met 1 Trp 1 Tyr 1 Phe 1 Lys

The following facts were observed:

- Edman degradation gave

- CNBr treatment yielded a pentapeptide and a tripeptide containing phenylalanine.
- Chymotrypsin treatment yielded a tetrapeptide containing a C-terminal indole amino acid and two dipeptides.
- Trypsin treatment yielded a tetrapeptide, a dipeptide, and free Lys and Phe.
- Clostripain yielded a pentapeptide, a dipeptide, and free Phe.

What is the amino acid sequence of this octapeptide?

- 7. Solving the Sequence of an Oligopeptide from Sequence Analysis Data** Amino acid analysis of an octapeptide gave the following results:

1 Ala 1 Arg 1 Asp 1 Gly 3 Ile 1 Val 1 NH₄⁺

The following facts were observed:

- Trypsin treatment yielded a pentapeptide and a tripeptide.
- Chemical reduction of the free α -COOH and subsequent acid hydrolysis yielded 2-aminopropanol.
- Partial acid hydrolysis of the tryptic pentapeptide yielded, among other products, two dipeptides, each of which contained C-terminal isoleucine. One of these dipeptides migrated as an anionic species upon electrophoresis at neutral pH.
- The tryptic tripeptide was degraded in an Edman sequenator, yielding first A, then B:

What is an amino acid sequence of the octapeptide? Four sequences are possible, but only one suits the authors. Why?

- 8. Solving the Sequence of an Oligopeptide from Sequence Analysis Data** An octapeptide consisting of 2 Gly, 1 Lys, 1 Met, 1 Pro, 1 Arg,

1 Trp, and 1 Tyr was subjected to sequence studies. The following was found:

- a. Edman degradation yielded

- b. Upon treatment with carboxypeptidases A, B, and Y, only carboxypeptidase Y had any effect.
 c. Trypsin treatment gave two tripeptides and a dipeptide.
 d. Chymotrypsin treatment gave two tripeptides and a dipeptide. Acid hydrolysis of the dipeptide yielded only Gly.
 e. Cyanogen bromide treatment yielded two tetrapeptides.
 f. Clostripain treatment gave a pentapeptide and a tripeptide.
 What is the amino acid sequence of this octapeptide?

9. Solving the Sequence of an Oligopeptide from Sequence Analysis Data

Amino acid analysis of an oligopeptide containing nine residues revealed the presence of the following amino acids:

Arg Cys Gly Leu Met Pro Tyr Val

The following was found:

- a. Carboxypeptidase A treatment yielded no free amino acid.
 b. Edman analysis of the intact oligopeptide released

- c. Neither trypsin nor chymotrypsin treatment of the nonapeptide released smaller fragments. However, combined trypsin and chymotrypsin treatment liberated free Arg.
 d. CNBr treatment of the eight-residue fragment left after combined trypsin and chymotrypsin action yielded a six-residue fragment containing Cys, Gly, Pro, Tyr, and Val and a dipeptide.
 e. Treatment of the six-residue fragment with β -mercaptoethanol yielded two tripeptides. Brief Edman analysis of the tripeptide mixture yielded only PTH-Cys. (The sequence of each tripeptide, as read from the N-terminal end, is alphabetical if the one-letter designation for amino acids is used.)

What is the amino acid sequence of this nonapeptide?

10. Describe the Solid-Phase Chemical Synthesis of a Small Peptide

Describe the synthesis of the dipeptide Lys-Ala by Merrifield's solid-phase chemical method of peptide synthesis. What pitfalls might be encountered if you attempted to add a leucine residue to Lys-Ala to make a tripeptide?

11. Identify Proteins Using BLAST Searches of Peptide Fragment Sequences

Go to the National Center for Biotechnology Information website at <http://www.ncbi.nlm.nih.gov/>. From the menu of Popular Resources on the right-hand side, click on "BLAST." Under the Basic BLAST heading on the new page that comes up, click on "protein blast." In the Enter Query Sequence box at the top of the page that comes up, enter the following sequence: NQMMKSRN-LTKDRCKP. Confirm that the database under "Choose Search Set" is set on "nr" (nonredundant protein sequences), then click the BLAST button at the bottom of the page to see the results of your search. Next, enter this sequence from a different protein: SLQTASAPDVYAIGECA. Identify the proteins from which these sequences were derived.

12. Calculate the Mass of a Protein from Mass Spectrometric m/z Values

Electrospray ionization mass spectrometry (ESI-MS) of the polypeptide chain of myoglobin yielded a series of m/z peaks (similar to those shown in Figure 5.14 for aerolysin K). Two successive peaks had m/z values of 1304.7 and 1413.2, respectively. Calculate the mass of the myoglobin polypeptide chain from these data.

13. Phosphorylation of Proteins Introduces New Properties

Phosphoproteins are formed when a phosphate group is esterified to an —OH group of a Ser, Thr, or Tyr side chain. At typical cellular pH values, this phosphate group bears two negative charges ($-\text{OPO}_3^{2-}$). Compare this side-chain modification with the 20 side chains of the common amino acids found in proteins and comment on the novel properties that it introduces into side-chain possibilities.

14. Binding of Ligands to a Protein

A pharmaceutical company studied the binding of three different compounds, X, Y and Z, to a particular protein of interest. For each compound, the fractional saturation (ν ; see Section 5.7b) was determined as a function of concentration. The results are shown in the figure. Which of the three compounds has the strongest affinity for the protein? Explain.

15. Using Graphical Analysis to Determine the K_d for the Interaction between a Protein and Its Ligand

A quantitative study of the interaction of a protein with its ligand yielded the following results:

Ligand concentration (mM)	1	2	3	4	5	6	9	12
ν (moles of ligand bound per mole of protein)	0.28	0.45	0.56	0.60	0.71	0.75	0.79	0.83

Plot a graph of $[L]$ versus ν . Determine K_D , the dissociation constant for the interaction between the protein and its ligand, from the graph.

- 16.** A protein can bind either of two different ligands, A and B. The protein's K_D for A is 0.3 mM. The protein's K_D for B is 1 mM. Calculate % saturation of the protein with A at concentrations of ligand equal to 0.1 mM, 0.2 mM, 0.5 mM, 1 mM, and 2 mM. Repeat the calculations for ligand B at these concentrations. Describe the relationship between K_D and relative affinity of the protein for ligands A and B.

Biochemistry on the Web

- 17. Exploring the ExPASy Proteomics Website** The human insulin receptor substrate-1 (IRS-1) is designated protein P35568 in the protein knowledge base on the ExPASy Website. Log onto <https://www.expasy.org>. Type "peptide mass tool" in the search box and click

“Enter” on your computer. In the results page that displays, scroll down and click on the “PeptideMass” resource. Then click on “Browse the resource website.” In the empty “Search” box, enter “P35568” as the accession number and click the “perform” button to see the results of trypsin digestion of IRS-1. How many amino acids does IRS-1 have? What is the average molecular mass of IRS-1? What is the amino acid sequence of the tryptic peptide of IRS-1 that has a mass of 1741.9629?

18. **Write a General Chemical Mechanism for Protease Reactions** Proteases such as trypsin and chymotrypsin cleave proteins at different sites, but both use the same reaction mechanism. Based on your knowledge of organic chemistry, suggest a “universal” protease reaction mechanism for hydrolysis of the peptide bond.
19. **Hemoglobin Mutations and Their Effects on Hb Structure and Function** Hundreds of mutations have been described in the genes encoding the α - and β -globin subunits of hemoglobin.
 - a. Some of these mutations affect subunit interactions between the subunits. In an examination of the tertiary structure of globin chains, where would you expect to find amino acid changes in mutant globins that affect formation of the hemoglobin $\alpha_2\beta_2$ quaternary structure?
 - b. Other mutations, such as the S form of the β -globin chain, increase the tendency of hemoglobin tetramers to polymerize into very large structures. Where might you expect the amino acid substitutions to be in these mutants?
20. **S Values** The ribosomal complex is often subdivided into the so-called 50S and 30S subunits.
 - a. What do those “50S” and “30S” terms refer to?
 - b. What is the reason for these different “S” values?

Think-Pair-Share Question

Evaluation of Peptide Degradation Consider the peptide shown.

QVDGLMRTSEQMKNSRV

You are asked to apply three digestion methods sequentially using trypsin, chymotrypsin, and staphylococcal protease as the endopeptidases. In between each digestion, you are asked to perform an Edman degradation analysis of the N-terminal amino acids of the fragments generated. You were not told in which order the three endopeptidases are to be applied. There are six possible orders in which the three endopeptidases could be applied.

	First	Second	Third
Order 1	Trypsin	Chymotrypsin	St. protease
Order 2	Trypsin	St. protease	Chymotrypsin
Order 3	Chymotrypsin	St. protease	Trypsin
Order 4	Chymotrypsin	Trypsin	St. protease
Order 5	St. protease	Trypsin	Chymotrypsin
Order 6	St. protease	Chymotrypsin	Trypsin

Select at least three digestion orders from the six shown; another student can select the remaining three. For each three-step digestion, determine the fragments that would be generated and the results one would obtain from the Edman degradation in between each digestion. Discuss whether the order of endopeptidase treatment leads to different end results (the results for the final Edman degradation reaction).

◀ Like the Greek sea god Proteus, who could assume different forms, proteins act through changes in conformation. Proteins (from the Greek *proteios*, meaning “primary”) are the primary agents of biological function. (“Proteus, Old Man of the Sea, Roman period mosaic, from Thessalonika, 1st century a.d. National Archaeological Museum, Athens/Ancient Art and Architecture Collection Ltd./Bridgeman Art Library, London/New York)

Essential Question

Proteins are the agents of biological function. They achieve this remarkable status through the intricate architectures they adopt by the process of protein folding. The forces of chemical bonding drive this formation of protein structure and the functions that follow. **How do the forces of chemical bonding determine the formation, stability, and myriad functions of proteins?**

Nearly all biological processes involve the specialized functions of one or more protein molecules. Proteins function to produce other proteins, control all aspects of cellular metabolism, regulate the movement of various molecular and ionic species across membranes, convert and store cellular energy, and carry out many other activities. Essentially all of the information required to initiate, conduct, and regulate each of these functions must be contained in the structure of the protein itself. The previous chapter described the details of protein primary structure. However, proteins do not normally exist as fully extended polypeptide chains, but rather as compact structures that biochemists refer to as *folded*. The ability of a particular protein to carry out its function in nature is normally determined by its overall three-dimensional shape, or *conformation*.

This chapter reveals and elaborates upon the exquisite beauty of protein structures and focuses on the overarching principles that link protein structure and function:

1. Function depends on structure.
2. Structure depends both on amino acid sequence and on weak, noncovalent forces.
3. The number of protein folding patterns is very large but finite.
4. The structures of globular proteins are marginally stable.
5. Marginal stability facilitates motion.
6. Motion enables function.

Key Questions

- 6.1 What Noncovalent Interactions Stabilize the Higher Levels of Protein Structure?
- 6.2 What Role Does the Amino Acid Sequence Play in Protein Structure?
- 6.3 What Are the Elements of Secondary Structure in Proteins, and How Are They Formed?
- 6.4 How Do Polypeptides Fold into Three-Dimensional Protein Structures?
- 6.5 How Do Protein Subunits Interact at the Quaternary Level of Protein Structure?

6.1 What Noncovalent Interactions Stabilize the Higher Levels of Protein Structure?

The amino acid sequence (primary structure) of any protein is dictated by covalent bonds, but the higher levels of structure—secondary, tertiary, and quaternary—are formed and stabilized by weak, noncovalent interactions (for example, the ionic interaction shown in Figure 6.1). Hydrogen bonds, hydrophobic interactions, electrostatic bonds, and van der Waals forces all contribute to protein conformation. The stabilization free energies afforded by each of these interactions may be highly dependent on the local environment within the protein, but certain generalizations can still be made.

6.1a Hydrogen Bonds Are Formed Whenever Possible

Hydrogen bonds are generally made wherever possible within a given protein structure. In most protein structures that have been examined to date, component atoms of the peptide backbone tend to form hydrogen bonds with one another. Furthermore, side chains capable of forming H bonds are usually located on the protein surface and form such bonds either with the water solvent or with other surface residues. The strengths of hydrogen bonds depend to some extent on environment. The difference in energy between a side chain hydrogen bonded to water and that same side chain hydrogen bonded to another side chain is usually quite small. On the other hand, a hydrogen bond in the protein interior, away from bulk solvent, can provide substantial stabilization energy to the protein. Although each hydrogen bond may contribute an average of only a few kilojoules per mole in stabilization energy for the protein structure, the number of H bonds formed in the typical protein is very large. For example, in α -helices, the C=O and N—H groups of every interior residue participate in H bonds. The importance of H bonds in protein structure cannot be overstated.

6.1b Hydrophobic Interactions Drive Protein Folding

Hydrophobic “bonds,” or, more accurately, *interactions*, form because nonpolar side chains of amino acids and other nonpolar solutes prefer to cluster in a nonpolar environment rather than to intercalate in a polar solvent such as water. The forming of hydrophobic “bonds” minimizes the interaction of nonpolar residues with water and is therefore highly favorable. Such clustering is entropically driven, and it is, in fact, the principal impetus for protein folding. The side chains of the amino acids in the interior or core of the protein structure are almost exclusively hydrophobic. Polar amino acids are much less common in the interior of a protein, but the protein surface may consist of both polar and nonpolar residues.

Figure 6.1 An electrostatic interaction between the ϵ -amino group of a lysine and the γ -carboxyl group of a glutamate. (a) The general case, and (b) the same interaction in a particular protein. The protein is IRAK-4 kinase, an enzyme that phosphorylates other proteins (PDB id = 2NRY). The interaction shown is between Lys²¹³ (left) and Glu²³³ (right).

6.1c Ionic Interactions Usually Occur on the Protein Surface

Ionic interactions arise either as electrostatic attractions between opposite charges or repulsions between like charges. Amino acid side chains can carry positive charges, as in the case of lysine, arginine, and histidine, or negative charges, as in aspartate and glutamate. In addition, the N-terminal and C-terminal residues of a protein or peptide chain usually exist in ionized states and carry positive or negative charges, respectively. All of these may experience ionic interactions in a protein structure. Charged residues are normally located on the protein surface, where they interact optimally with the water solvent. It is energetically unfavorable for an ionized residue to be located in the hydrophobic core of the protein. Ionic interactions between charged groups on a protein surface are often complicated by the presence of salts in the solution. For example, the ability of a positively charged lysine to attract a nearby negative glutamate may be weakened by dissolved salts such as NaCl (Figure 6.1). The Na^+ and Cl^- ions are highly mobile, compact units of charge, compared to the amino acid side chains, and thus compete effectively for charged sites on the protein. In this manner, ionic interactions among amino acid residues on protein surfaces may be damped out by high concentrations of salts. Nevertheless, these interactions are important for protein stability.

6.1d Van der Waals Interactions Are Ubiquitous

Both attractive forces and repulsive forces are included in van der Waals interactions. The attractive forces are due primarily to instantaneous dipole-induced dipole interactions that arise because of fluctuations in the electron charge distributions of adjacent nonbonded atoms. Individual van der Waals interactions are weak ones (with stabilization energies of 0.4 to 4.0 kJ/mol), but many such interactions occur in a typical protein, and by sheer force of numbers, they can represent a significant contribution to the stability of a protein.

Chemistry in History

César Milstein

César Milstein (1927–2002) was born and raised in Argentina. An older cousin who studied snake venoms aroused César's interest in science at the age of 8. He was active in student politics in college, campaigning against the Peronist government's policies of the time. After graduating with a bachelor's in chemistry, Milstein spent a year hitchhiking around Europe with his wife Celia. Returning to Buenos Aires, he worked in a clinical chemistry lab to support his graduate studies on kinetics of aldehyde dehydrogenase, earning his PhD. in 1957. Milstein moved to England where he earned a second PhD from the University of Cambridge, working closely

with Frederick Sanger on phosphoglucomutase. Later at the MRC Laboratory for Molecular Biology, Sanger encouraged Milstein to study immunology. Milstein and his student Georges Köhler pioneered the creation of hybridomas – fusions of antibody-producing B cells and myeloma cells that are immortal and that produce monoclonal antibodies. For this ground-breaking work, Milstein and Köhler shared in the Nobel Prize in Medicine or Physiology in 1984. Today monoclonal antibodies have found hundreds of applications in the treatment of cancer, infectious diseases and many other pathologies, including COVID-19.

6.2 What Role Does the Amino Acid Sequence Play in Protein Structure?

As described in Section 6.1, many different forces work together to determine the overall three-dimensional structure of a protein. These forces operate both within the protein structure itself and between the protein and the water solvent. How, then, does nature dictate the manner of protein folding to generate the three-dimensional structure that optimizes and balances these many forces? *All of the information necessary for folding the peptide chain into its native structure is contained in the amino acid sequence of the peptide.*

Figure 6.2 The amide or peptide bond planes are joined by the tetrahedral bonds of the α -carbon. The rotation parameters are ϕ and ψ . The conformation shown corresponds to $\phi = 180^\circ$ and $\psi = 180^\circ$. Note that positive values of ϕ and ψ correspond to clockwise rotation as viewed from C_α . Starting from 0° , a rotation of 180° in the clockwise direction ($+180^\circ$) is equivalent to a rotation of 180° in the counterclockwise direction (-180°).

Just how proteins recognize and interpret the information that is stored in the amino acid sequence is not yet well understood. Certain loci along the peptide chain may act as nucleation points, which initiate folding processes that eventually lead to the correct structures. Regardless of how this process operates, it must take the protein correctly to the final native structure. Along the way, local energy-minimum states different from the native state itself must be avoided.

6.3 What Are the Elements of Secondary Structure in Proteins, and How Are They Formed?

Any discussion of protein folding and structure must begin with the *peptide bond*, the fundamental structural unit in all proteins. As we saw in Chapter 4, the resonance structures experienced by a peptide bond constrain six atoms—the oxygen, carbon, nitrogen, and hydrogen atoms of the peptide group, as well as the adjacent α -carbons—to lie in a plane. The resonance stabilization energy of this planar structure is approximately 88 kJ/mol, and substantial energy is required to twist the structure about the C—N bond. A twist of θ degrees involves a twist energy of $88 \sin^2 \theta$ kJ/mol.

6.3a The Amide Plane Is a Fundamental Determinant of All Protein Structure

The planarity of the peptide bond means that there are only two degrees of freedom per residue for the peptide chain. Rotation is allowed about the bond linking the α -carbon with its carbonyl carbon and also about the bond linking the α -carbon with its amide nitrogen. As shown in Figure 6.2, each α -carbon is the joining point for two planes defined by peptide bonds. The angle about the C_α —N bond is denoted by the Greek letter ϕ (phi), and that about the C_α —C is denoted by ψ (psi). For either of these bond angles, a value of 0° corresponds to an orientation with the amide plane bisecting the H— C_α —R (side-chain) angle and a *cis* conformation of the main chain around the rotating bond in question (Figure 6.3).

Figure 6.3 Many of the possible conformations about an α -carbon between two peptide planes are forbidden because of steric crowding. Several noteworthy examples are shown here.

Note: The formal IUPAC-IUB Commission on Biochemical Nomenclature convention for the definition of the torsion angles ϕ and ψ in a polypeptide chain (*Biochemistry* 9:3471–3479, 1970) is different from that used here, where the C_α atom serves as the point of reference for both rotations, but the result is the same.

The entire path of the peptide backbone in a protein is known if the ϕ and ψ rotation angles are all specified. Some values of ϕ and ψ are not allowed due to steric interference between nonbonded atoms. As shown in Figure 6.3, values of $\phi = 180^\circ$ and $\psi = 0^\circ$ are not allowed because of the forbidden overlap of the N—H hydrogens. Similarly, $\phi = 0^\circ$ and $\psi = 180^\circ$ are forbidden because of unfavorable overlap between the carbonyl oxygens.

A plot of ϕ values against ψ values, first described by G. N. Ramachandran and his colleagues in Madras, India, revealed the distribution of allowed values in a protein or in a family of proteins. A typical **Ramachandran plot** is shown in Figure 6.4. Note the clustering of ϕ and ψ values in a few regions of the plot. Most combinations of ϕ and ψ are sterically forbidden, and the corresponding regions of the Ramachandran plot are sparsely populated. The combinations that are sterically allowed represent the subclasses of structure described in the remainder of this section.

Figure 6.4 A Ramachandran diagram showing the sterically reasonable values of the angles ϕ and ψ . The shaded regions indicate particularly favorable values of these angles. Dots in purple indicate actual angles measured for 1000 residues (excluding glycine, for which a wider range of angles is permitted) in eight proteins. The lines running across the diagram (numbered +5 through +2 and -5 through -3) signify the number of amino acid residues per turn of the helix; “+” means right-handed helices; “-” means left-handed helices. (After Richardson, J. S., 1981. The anatomy and taxonomy of protein structure. *Advances in Protein Chemistry* **34**:167–339.)

6.3b The Alpha-Helix Is a Key Secondary Structure

The term *secondary structure* describes local conformations of the polypeptide that are stabilized by hydrogen bonds. In nearly all proteins, the hydrogen bonds that make up secondary structures involve the amide proton of one peptide group and the carbonyl oxygen of another, as shown in Figure 6.5. These structures tend to form in cooperative fashion and involve substantial portions of the peptide chain. When a number of hydrogen bonds form between portions of the peptide chain in this manner, two basic types of structures can result: **α -helices** and **β -pleated sheets**. (The R-groups (sidechains) of a protein may slightly alter the structures and stability of helices and sheets, but the H bonds between backbone N—H and C=O groups are the dominant stabilizing interactions in these structures.)

The earliest studies of protein secondary structure were those of William Astbury at the University of Leeds. Astbury carried out X-ray diffraction studies on wool and observed differences between unstretched wool fibers and stretched wool fibers. He proposed that the protein structure in unstretched fibers was a helix (which he called the **alpha form**). He also proposed that stretching caused the helical structures to uncoil,

A Deeper Look

Knowing What the Right Hand and Left Hand Are Doing

Certain conventions related to peptide bond angles and the “handedness” of biological structures are useful in any discussion of protein structure. To determine the ϕ and ψ angles between peptide planes, viewers should imagine themselves at the C_α carbon looking outward and should imagine starting from the $\phi = 0^\circ$, $\psi = 0^\circ$ conformation. From this perspective, positive values of ϕ correspond to clockwise rotations about the C_α —N bond of the plane that includes the adjacent N—H group. Similarly, positive values of ψ

correspond to clockwise rotations about the C_α —C bond of the plane that includes the adjacent C=O group.

Biological structures are often said to exhibit “right-hand” or “left-hand” twists. For all such structures, the sense of the twist can be ascertained by holding the structure in front of you and looking along the polymer backbone. If the twist is clockwise as one proceeds outward and through the structure, it is said to be right-handed. If the twist is counterclockwise, it is said to be left-handed.

Critical Developments in Biochemistry

X-ray Crystallography of Proteins

Most of the protein structures archived in the Protein Data Bank (PDB) were determined by X-ray crystallography. In this technique, the protein of interest must be purified and crystallized and then subjected to an intense X-ray beam. Atoms in the crystal diffract the X-ray beam to produce characteristic spots on a film or X-ray detector. Analysis of the resulting **diffraction pattern** (figure), combined with special techniques to determine the phase of the X-rays at each spot, reveals the arrangement and distribution of electrons in the protein crystal in an **electron density map**. This map can be interpreted to assign the locations of each atom in the structure (producing the **atomic model**). A crystallographic study produces two types of data—the coordinate files that include atomic positions for the final structure model, and the **structure factor file** that consists of the intensities and phases of the X-ray spots in the diffraction pattern. Appropriate software (the AstexViewer on the PDB website or PyMol <https://pymol.org>) can then be used to display an image of the protein, in a variety of formats.

The crystallization process is frequently difficult and limits the types of proteins that can be studied by X-ray crystallography. Very stable, rigid proteins that form well-ordered crystals work well, but marginally stable, very flexible proteins are less amenable to crystallographic analysis. Interestingly, many proteins are a mixture of very stable and very flexible domains, even in the crystalline state. The stable portions may produce good structure information, but the flexible portions may be invisible in the electron density maps and the resulting structure images, because their electron density is spread over a large space. The quality and accuracy of a crystal structure is defined by two parameters. The first of these is the **resolution**, which is the smallest distance that is resolved in the diffraction pattern. A value of 4 Å means poor resolution, whereas a value of 1.5 Å represents good resolution. The second criterion of accuracy is the **R-value**, which measures how well the atomic model is supported by the experimental data found in the structure factor file. A random set of atoms produces an R-value of about 0.63, whereas a perfect fit yields a value of 0. Typical values for published structures are about 0.20.

X-ray crystallography on a femtosecond timescale has been achieved using **X-ray free electron lasers (XFEL)**. In a free electron laser, a beam of electrons is accelerated to almost the speed of light and passed through a periodic array of magnets, creating pulses of radiation that are very short (10^{-15} s) and very bright (billions of times stronger than conventional X-rays). A stream of tiny crystals of the protein of interest is passed through the beam, and each intense X-ray pulse generates a diffraction pattern, usually burning up the crystal in the process. Many hundreds or even tens of thousands of these diffraction patterns are compiled into data sets that provide information on the ultrafast dynamics of protein molecules, such as conformation changes and absorption of light by molecular groups in the protein termed chromophores.

The workflow in X-ray crystallography.

yielding an extended structure (which he called the **beta form**). Astbury was the first to propose that hydrogen bonds between peptide groups contributed to stabilizing these structures.

In 1951, Linus Pauling, Robert Corey, and their colleagues at the California Institute of Technology summarized a large volume of crystallographic data in a set of dimensions for polypeptide chains. (A summary of data similar to what they reported is shown in Figure 4.14.) With these data in hand, Pauling, Corey, and Herman Branson proposed a new model for a helical structure in proteins, which they called the α -helix. The report from Caltech was of particular interest to Max Perutz in Cambridge, England, a crystallographer who was also interested in protein structure. By taking into account a critical but previously ignored feature of the X-ray data, Perutz realized that the α -helix existed in keratin, a protein from hair, and also in several other proteins. Since then, the α -helix has proved to be a fundamentally important peptide structure. Several representations of the α -helix are shown in Figure 6.6. One turn of the helix represents 3.6 amino acid residues. (A single turn of the α -helix involves 13 atoms from the O to the H of the H bond. For this reason, the α -helix is sometimes referred to as the 3.6₁₃ helix.)

Figure 6.6 Four different graphic representations of the α -helix. (a) A stick representation with H bonds as dotted lines, as originally conceptualized in Pauling's 1960 *The Nature of the Chemical Bond*. (b) Showing the arrangement of peptide planes in the helix. (c) A space-filling computer graphic presentation. (d) A "ribbon structure" with an inlaid stick figure, showing how the ribbon indicates the path of the polypeptide backbone.

Each amino acid residue extends **1.5 Å (0.15 nm)** along the helix axis. With **3.6 residues per turn**, this amounts to $3.6 \times 1.5 \text{ Å}$ or **5.4 Å (0.54 nm)** of travel along the helix axis per turn. This is referred to as the translation distance or the **pitch** of the helix. If one ignores side chains, the helix is about 6 Å in diameter. The side chains, extending outward from the core structure of the helix, are removed from steric interference with the polypeptide backbone. As can be seen in Figure 6.6, *each peptide carbonyl is hydrogen bonded to the peptide N—H group four residues farther up the chain*. Note that all of the H bonds lie parallel to the helix axis and all of the carbonyl groups are pointing in one direction along the helix axis while the N—H groups are pointing in the opposite direction. Recall that the entire path of the peptide backbone can be known if the ϕ and ψ twist angles are specified for each residue. The α -helix is formed if the values of ϕ are approximately -60° and the values of ψ are in the range of -45 to -50° . Figure 6.7 shows the structures of two proteins that contain α -helical segments. The number of residues involved in a given α -helix varies from helix to helix and from protein to protein. On average, there are about 10 residues per helix. Myoglobin, one of the first proteins in which α -helices were observed, has eight stretches of α -helix that form a box to contain the heme prosthetic group (see Figure 5.1).

Figure 6.7 The three-dimensional structures of two proteins that contain substantial amounts of α -helix. The helices are represented by the regularly coiled sections of the ribbon drawings. Myohemerythrin is the oxygen-carrying protein in certain invertebrates, including *Sipunculids*, a phylum of marine worm. β -Hemoglobin subunit: PDB id = 1HGA; myohemerythrin PDB id = 1A7D.

As shown in Figure 6.6, all of the hydrogen bonds point in the same direction along the α -helix axis. Each peptide bond possesses a dipole moment that arises from the polarities of the N—H and C=O groups, and because these groups are all aligned along the helix axis, the helix itself has a substantial dipole moment, with a partial positive

charge at the N-terminus and a partial negative charge at the C-terminus (Figure 6.8). Negatively charged ligands (e.g., phosphates) frequently bind to proteins near the N-terminus of an α -helix. By contrast, positively charged ligands are only rarely found to bind near the C-terminus of an α -helix.

In a typical α -helix of 12 (or n) residues, there are 8 (or $n - 4$) hydrogen bonds. As shown in Figure 6.9, the first 4 amide hydrogens and the last 4 carbonyl oxygens cannot participate in helix H bonds. Also, nonpolar residues situated near the helix termini can be exposed to solvent. Proteins frequently compensate for these problems by **helix capping**—providing H-bond partners for the otherwise bare N—H and C=O groups and folding other parts of the protein to foster hydrophobic contacts with exposed nonpolar residues at the helix termini.

With one exception, all of the twenty common amino acids are found frequently in alpha-helices. Proline (and hydroxyproline) act as helix breakers due to their unique structure, which limits the value of ϕ (i.e., rotation about the C_α —N bond).

6.3c The β -Pleated Sheet Is a Core Structure in Proteins

Another type of structure commonly observed in proteins also forms because of local, cooperative formation of hydrogen bonds. That is the pleated sheet, or β -structure, often called the **β -pleated sheet**. This structure was also first postulated by Pauling and Corey in 1951 and has now been observed in many natural proteins. A β -pleated sheet can be

Figure 6.9 Four N—H groups at the N-terminal end of an α -helix (*bottom*) and four C=O groups at the C-terminal end (*top*) lack partners for H-bond formation. The formation of H bonds with other nearby donor and acceptor groups is referred to as helix capping. Capping may also involve appropriate hydrophobic interactions that accommodate nonpolar side chains at the ends of helical segments.

Figure 6.8 The arrangement of N—H and C=O groups (each with an individual dipole moment) along the helix axis creates a large net dipole for the helix. Numbers indicate fractional charges on respective atoms.

Critical Developments in Biochemistry

In Bed with a Cold, Pauling Stumbles onto the α -Helix and a Nobel Prize*

As high technology continues to transform the modern biochemical laboratory, it is interesting to reflect on Linus Pauling's discovery of the α -helix. It involved only a piece of paper, a pencil, scissors, and a sick Linus Pauling, who had tired of reading detective novels. The story is told in the excellent book *The Eighth Day of Creation* by Horace Freeland Judson:

From the spring of 1948 through the spring of 1951 ... rivalry sputtered and blazed between Pauling's lab and (Sir Lawrence) Bragg's—over protein. The prize was to propose and verify in nature a general three-dimensional structure for the polypeptide chain. Pauling was working up from the simpler structures of components. In January 1948, he went to Oxford as a visiting professor for two terms, to lecture on the chemical bond and on molecular structure and biological specificity. "In Oxford, it was April, I believe, I caught cold. I went to bed, and read detective stories for a day, and got bored, and thought why don't I have a crack at that problem of alpha keratin." Confined, and still fingering the polypeptide chain in his mind, Pauling called for paper, pencil, and straightedge and attempted to reduce the problem to an almost Euclidean purity. "I took a sheet of paper—I still have this sheet of paper—and drew, rather roughly, the way that I thought a polypeptide chain would look if it were spread out into a plane." The repetitious herringbone of the chain he could stretch across the paper as simply as this—putting in lengths

and bond angles from memory.... He knew that the peptide bond, at the carbon-to-nitrogen link, was always rigid:

And this meant that the chain could turn corners only at the alpha carbons.... "I creased the paper in parallel creases through the alpha carbon atoms, so that I could bend it and make the bonds to the alpha carbons, along the chain, have tetrahedral value. And then I looked to see if I could form hydrogen bonds from one part of the chain to the next." He saw that if he folded the strip like a chain of paper dolls into a helix, and if he got the pitch of the screw right, hydrogen bonds could be shown to form, $N-H \cdots O=C$, three or four knuckles apart along the backbone, holding the helix in shape. After several tries, changing the angle of the parallel creases in order to adjust the pitch of the helix, he found one where the hydrogen bonds would drop into place, connecting the turns, as straight lines of the right length. He had a model.

*The discovery of the α -helix structure was only one of many achievements that led to Pauling's Nobel Prize in Chemistry in 1954. The official citation for the prize was "for his research into the nature of the chemical bond and its application to the elucidation of the structure of complex substances."

visualized by laying thin, pleated strips of paper side by side to make a "pleated sheet" of paper (Figure 6.10). Each strip of paper can then be pictured as a single peptide strand in which the peptide backbone makes a zigzag pattern along the strip, with the α -carbons lying at the folds of the pleats. The pleated sheet can exist in both parallel and antiparallel forms.

In the **parallel β -pleated sheet**, adjacent chains run in the same direction. In the **antiparallel β -pleated sheet**, adjacent strands run in opposite directions. The arrangement of successive amide planes in a β -sheet has a pleated appearance due to the tetrahedral nature of the C_α atom. It is important to note that the hydrogen bonds in this structure are essentially *interstrand* rather than *intrastrand*. Optimum formation of H bonds in the parallel pleated sheet results in a slightly less extended conformation than in the antiparallel sheet. The H bonds thus formed in the parallel β -sheet are bent significantly. The distance between residues is 0.347 nm for the antiparallel pleated sheet, but only 0.325 nm for the parallel pleated sheet. Note that the side chains in the pleated sheet are oriented perpendicular or normal to the plane of the sheet, extending out from the plane on alternating sides.

Parallel β -sheets tend to be more regular than antiparallel β -sheets. As can be seen in Figure 6.4, typical ϕ , ψ values for a parallel β -sheet are $\phi = -120^\circ$, $\psi = 105^\circ$, and typical values for an antiparallel β -sheet are $\phi = -135^\circ$, $\psi = 140^\circ$. However, the range of ϕ and ψ angles for the peptide bonds in parallel sheets is much smaller than that for antiparallel sheets. Parallel sheets are typically large structures; those composed of fewer than

Figure 6.10 β -sheet structures in proteins. (a) A “pleated sheet” of paper with an antiparallel β -sheet drawn on it. (b) Hydrogen bonds in a parallel β -sheet. (c) Hydrogen bonds in an antiparallel β -sheet.

five strands are rare. Antiparallel sheets, however, may consist of as few as two strands. Parallel sheets characteristically distribute hydrophobic side chains on both sides of the sheet, whereas antiparallel sheets are usually arranged with all their hydrophobic residues on one side of the sheet. This requires an alternation of hydrophilic and hydrophobic residues in the primary structure of peptides involved in antiparallel β -sheets because every other side chain projects to the same side of the sheet (Figure 6.10).

6.3d Helix–Sheet Composites Provide Flexibility and Strength in Spider Silk

Although the intricate designs of spider webs are eye (and fly) catching, it might be argued that the composition of web silk itself is even more remarkable. Spider silk, a form of keratin, is synthesized in special glands in the spider's abdomen. The silk strands produced by these glands are both strong and elastic. *Dragline silk* (that from which the spider hangs) has a tensile strength of 200,000 psi (pounds per square inch)—stronger than steel and similar to Kevlar, the synthetic material used in bulletproof vests! This same silk fiber is also flexible enough to withstand strong winds and other natural stresses. This combination of strength and flexibility derives from the *composite nature* of spider silk. As keratin protein is extruded from the spider's glands, it endures shearing forces that break the H bonds stabilizing keratin α -helices (Figure 6.11). These regions then form microcrystalline arrays of β -sheets. These microcrystals are surrounded by the keratin strands, which adopt a highly disordered state composed of α -helices and random coil structures. The β -sheet microcrystals contribute strength, and the disordered array of helix and coil make the silk strand flexible. The resulting silk strand resembles modern human-engineered composite materials and products, such as tennis racquets.

6.3e β -Turns Allow the Protein Strand to Change Direction

Polypeptide chains must possess the capacity to bend, turn, and reorient themselves to produce compact, globular structures. A simple structure observed in many proteins is the **β -turn** (also known as the *tight turn* or *β -bend*), in which the peptide chain forms a tight loop with the carbonyl oxygen of one residue hydrogen bonded with the amide proton of the residue three positions down the chain. This H bond makes the β -turn a relatively stable structure. As shown in Figure 6.12, the β -turn allows the protein to reverse the direction of its peptide chain. This figure shows the two major types of β -turns, but a number of less common types are also found in protein structures. Because it lacks a side chain, glycine

Figure 6.11 Spider web silks (a) are composites of α -helices and β -sheets. The radial strands of webs (b), (c), (d) must be strong and rigid; silks in radial strands contain a higher percentage of β -sheets. The circumferential strands (termed *capture silk*) must be flexible (to absorb the impact of flying insects); capture silk contains a higher percentage of α -helices. Spiders typically have several different silk gland spinnerets, which secrete different silks of differing composition. Spiders have inhabited the earth for about 470 million years.

Figure 6.12 The structures of two kinds of β -turns (also called tight turns or β -bends). Four residues are required to form a β -turn. (a) Type I; (b) Type II.

is sterically the most adaptable of the amino acids, and it accommodates conveniently to other steric constraints in the β -turn. Proline, however, has a cyclic structure and a fixed ϕ angle, so, to some extent, it forces the formation of a β -turn; in many cases this facilitates the turning of a polypeptide chain upon itself. Such bends promote formation of antiparallel β -pleated sheets. Type I turns (Figure 6.12) are more common than type II. Proline fits best in the 3 position of the type I turn. In the type II turn, proline is preferred at the 2 position, whereas the 3 position prefers glycine or small polar residues.

6.4 | How Do Polypeptides Fold into Three-Dimensional Protein Structures?

The arrangement of all atoms of a single polypeptide chain in three-dimensional space is referred to as its **tertiary structure**. As discussed in Section 6.2 all of the information needed to fold the protein into its native tertiary structure is contained within the primary structure of the peptide chain itself. Sometimes proteins known as **chaperones** assist in the process of protein folding in the cell, but proteins in dilute solution can be unfolded and refolded without the assistance of such chaperones.

The first determinations of the tertiary structure of a protein were by John Kendrew and Max Perutz. Kendrew's structure of myoglobin and Perutz's structure of hemoglobin, reported in the late 1950s, were each the result of more than 20 years of work. Ever since these first protein structures were elucidated, biochemists have sought to understand the principles by which proteins adopt their remarkable structures. Vigorous work in many laboratories has slowly brought important principles to light:

- Secondary structures—helices and sheets—form whenever possible as a consequence of the formation of large numbers of hydrogen bonds.
- α -Helices and β -sheets often associate and pack close together in the protein. No protein is stable as a single-layer structure, for reasons that become apparent later. There are a few common methods for such packing to occur.
- Because the peptide segments between secondary structures in the protein tend to be short and direct, the peptide does not execute complicated twists and knots as it moves from one region of secondary structure to another.
- Proteins generally fold so as to form the most stable structures possible. The stability of most proteins arises from (1) the formation of large numbers of intramolecular hydrogen bonds and (2) the reduction in the surface area accessible to solvent that occurs upon folding.

Two factors lie at the heart of these four principles. First, proteins are typically a mixture of hydrophilic and hydrophobic amino acids. Why is this important? Imagine a protein that is composed only of polar and charged amino acids. In such a protein, every side chain could hydrogen bond to water. This would leave no reason for the protein to form a compact, folded structure.

Now consider a protein composed of a mixture of hydrophilic and hydrophobic residues. In this case, the hydrophobic side chains cannot form H bonds with water, and their presence will disrupt the hydrogen-bonding structure of water itself. *To minimize this, the hydrophobic groups will tend to cluster together. This **hydrophobic effect** induces formation of a compact structure—the folded protein.*

A potential problem with this rather simple folding model is that polar backbone N—H and C=O groups on the hydrophobic residues accompany the hydrophobic side chains into the folded protein interior. This would be energetically costly to the protein, but the actual result is that the polar backbone groups form H bonds with one another, so that the polar backbone N—H and C=O moieties are stabilized in α -helices and β -sheets in the protein interior.

A Deeper Look

The Coiled-Coil Motif in Proteins

The coiled-coil motif was first identified in 1953 by Linus Pauling, Robert Corey, and Francis Crick as the main structural element of fibrous proteins such as keratin and myosin. Since then, many proteins have been found to contain one or more coiled-coil segments or domains. A coiled coil is a bundle of α -helices that are wound into a superhelix. Two, three, or four helical segments may be found in the bundle, and they may be arranged parallel or antiparallel to one another. Coiled coils are characterized by a distinctive and regular packing of side chains in the core of the bundle. This regular meshing of side chains

requires that they occupy equivalent positions turn after turn. This is not possible for undistorted α -helices, which have 3.6 residues per turn. The positions of side chains on their surface shift continuously along the helix surface (see Figure 6.13c). However, giving the right-handed α -helix a left-handed twist reduces the number of residues per turn to 3.5, and because $3.5 \times 2 = 7.0$, the positions of the side chains repeat after two turns (7 residues). Thus, a **heptad repeat** pattern in the peptide sequence is diagnostic of a coiled-coil structure. Figure 1 shows a sampling of coiled-coil structures (highlighted in color) in various proteins.

6.4a Fibrous Proteins Usually Play a Structural Role

In Chapter 5, we saw that proteins can be grouped into three large classes based on their structure and solubility: *fibrous proteins*, *globular proteins*, and *membrane proteins*. Fibrous proteins contain polypeptide chains organized approximately parallel along a single axis, producing long fibers or large sheets. Such proteins tend to be mechanically strong and resistant to solubilization in water and dilute salt solutions. Fibrous proteins often play a structural role in nature (see Chapter 5).

α -Keratin The α -keratins are the predominant constituents of claws, fingernails, hair, and horns in mammals. As their name suggests, the structure of the α -keratins is dominated by α -helical segments of polypeptide. The amino acid sequence of α -keratin subunits is composed of central α -helix-rich rod domains about 311 to 314 residues in length, flanked by nonhelical N- and C-terminal domains of varying size and composition (Figure 6.13a). The structure of the central rod domain of a typical α -keratin is shown in Figure 6.13b. Pairs of right-handed α -helices wrap around each other to form a left-twisted **coiled coil**. X-ray diffraction data show that these structures resemble α -helices, but with a pitch of 0.51 nm rather than the expected 0.54 nm. This is consistent with a tilt of the helix relative to the long axis of the coiled coil (and the keratin fiber) in Figure 6.13.

The amino acid sequence of the central rod segments of α -keratin consists of quasi-repeating seven-residue segments of the form $(a-b-c-d-e-f-g)_n$. These units are not true repeats, but residues *a* and *d* are usually nonpolar amino acids. In α -helices, with 3.6 residues per turn, these nonpolar residues are arranged in an inclined row or stripe that twists around the helix axis (Figure 6.13c). These nonpolar residues would make the helix highly unstable if they were exposed to solvent, but the association of hydrophobic stripes on two α -helices to form the two-stranded coiled coil effectively buries

Figure 6.13 (a) Both type I and type II α -keratin molecules have sequences consisting of long, central rod domains with terminal cap domains. The numbers of amino acid residues in each domain are indicated. Asterisks denote domains of variable length. (b) The rod domains form coiled coils consisting of left-twisted right-handed α -helices. These coiled coils form protofilaments that then wind around each other in a right-handed twist. Keratin filaments consist of twisted protofibrils (each a bundle of four coiled coils). (c) Periodicity of hydrophobic residues. (Adapted from Steinert, P., and Parry, D., 1985. Intermediate filaments: Conformity and diversity of expression and structure. *Annual Review of Cell Biology* 1:41–65; and Cohlberg, J., 1993. Textbook error: The structure of alpha-keratin. *Trends in Biochemical Sciences* 18:360–362.)

the hydrophobic residues and forms a highly stable structure (Figure 6.13). The helices sacrifice some stability in assuming this twisted conformation, but they gain stabilization energy from the packing of side chains between the helices. In other forms of keratin, covalent disulfide bonds form between cysteine residues of adjacent molecules, making the overall structure even more rigid, inextensible, and insoluble—important properties for structures such as claws, fingernails, hair, and horns. How and where these disulfides form determines the amount of curling in hair and wool fibers. When a hairstylist creates a permanent wave (simply called a perm) in a hair salon, disulfides in the hair are first reduced and cleaved, then reorganized and reoxidized to change the degree of curl or wave. In contrast, a “set” that is created by wetting the hair, setting it with curlers, and then drying it represents merely a rearrangement of the hydrogen bonds between helices and between fibers. (On humid or rainy days, the hydrogen bonds in curled hair may rearrange, and the hair becomes frizzy.)

Fibroin and β -Keratin: β -Sheet Proteins The **fibroin** proteins found in silk fibers in the cocoons of the silkworm, *Bombyx mori*, and also in spiderwebs represent another type of fibrous protein. These are composed of stacked antiparallel β -sheets, as shown in Figure 6.14. In the polypeptide sequence of silk proteins, there are large stretches in which every other residue is a glycine. As previously mentioned, the residues of a β -sheet extend alternately above and below the plane of the sheet. As a result, the glycines all end up on one side of the sheet and the other residues (mainly alanines and serines) compose the opposite surface of the sheet. Pairs of β -sheets can then pack snugly together (glycine surface to glycine surface or alanine–serine surface to alanine–serine surface). The β -keratins found in bird feathers are also made up of stacked β -sheets.

Collagen: A Triple Helix Collagen is a rigid, inextensible fibrous protein that is a principal constituent of connective tissue in animals, including tendons, cartilage, bones, teeth, skin, and blood vessels. The high tensile strength of collagen fibers in these structures makes possible the various animal activities such as running and jumping that put severe stresses on joints and skeleton. Broken bones and tendon and cartilage injuries to knees, elbows, and other joints involve tears or hyperextensions of the collagen matrix in these tissues.

The basic structural unit of collagen is **tropocollagen**, which has a molecular weight of 285,000 and consists of three intertwined polypeptide chains, each about 1000 amino acids in length. Tropocollagen molecules are about 300 nm long and only about 1.4 nm

Figure 6.14 Silk fibroin consists of a unique stacked array of β -sheets. The primary structure of fibroin molecules consists of long stretches of alternating glycine and alanine or serine residues. When the sheets stack, the more bulky alanine and serine residues on one side of a sheet interdigitate with similar residues on an adjoining sheet. Glycine hydrogens on the alternating faces interdigitate in a similar manner, but with a smaller intersheet spacing.

in diameter. Several kinds of collagen have been identified. *Type I collagen*, which is the most common, consists of two identical peptide chains designated $\alpha 1(I)$ and one different chain designated $\alpha 2(I)$. Type I collagen predominates in bones, tendons, and skin. *Type II collagen*, found in cartilage, and *type III collagen*, found in blood vessels, consist of three identical polypeptide chains.

Collagen has an amino acid composition that is unique and is crucial to its three-dimensional structure and its characteristic physical properties. Nearly one residue out of three is a glycine, and the proline content is also unusually high. Three unusual modified amino acids are also found in collagen: 4-hydroxyproline (Hyp), 3-hydroxyproline, and 5-hydroxylysine (Hyl) (Figure 4.4). Proline and Hyp together compose up to 30% of the residues of collagen. Interestingly, these three amino acids are formed from normal proline and lysine *after* the collagen polypeptides are synthesized. The modifications are effected by two enzymes: *prolyl hydroxylase* and *lysyl hydroxylase*. The prolyl hydroxylase reaction (Figure 6.15) requires molecular oxygen, α -ketoglutarate, and ascorbic acid (vitamin C) and is activated by Fe^{2+} . The hydroxylation of lysine is similar.

Because of their high content of glycine, proline, and hydroxyproline, collagen fibers are incapable of forming traditional structures such as α -helices and β -sheets. Instead, collagen polypeptides intertwine to form a unique right-handed **triple helix**, with each of the three strands arranged in a left-handed helical fashion (Figure 6.16). Compared with the α -helix, the collagen helix is much more extended, with a rise per residue along the triple helix axis of 2.9 Å (versus 1.5 Å for the α -helix). There are about 3.3 residues per turn of each of these helices. *The triple helix is a structure that forms to accommodate the unique composition and sequence of collagen.* Long stretches of the polypeptide sequence are repeats of a Gly-*x*-*y* motif, where *x* is frequently Pro and *y* is frequently Pro or Hyp. In the triple helix, every third residue faces or contacts the crowded center of the structure. This area is so crowded that only Gly can fit, and thus every third residue must be a Gly (as observed). Moreover, the triple helix is a *staggered* structure, such that Gly residues from the three strands stack along the center of the triple helix and the Gly from one strand lies adjacent to an *x* residue from the second strand and a *y* from the third. This allows the N—H of each Gly residue to hydrogen bond with the C=O of the adjacent *x* residue. The triple helix structure is further stabilized and strengthened by the formation of interchain H bonds involving hydroxyproline.

Figure 6.15 Hydroxylation of proline residues is catalyzed by prolyl hydroxylase. The reaction requires α -ketoglutarate and ascorbic acid (vitamin C).

Calculation of the structures of collagen models. Role of inter-chain interactions in determining the triple-helical coiled-coil conformation. I. Poly(glycyl-prolyl-prolyl). *Journal of Polymer Science Symposium* 54:171–200.)

6.4b Globular Proteins Mediate Cellular Function

Fibrous proteins, although interesting for their structural properties, represent only a small percentage of the proteins found in nature. **Globular proteins**, so named for their approximately spherical shape, are far more numerous. The diversity of protein structures found in nature reflects the remarkable variety of functions performed by proteins—binding, catalysis, regulation, transport, immunity, cellular signaling, and more. The functional diversity and versatility derive in turn from the large number of folded structures that polypeptide chains can adopt and the varied chemistry of the side chains of the 20 common amino acids. Remarkably, this diversity of structure and function derives from a relatively small number of principles and themes of protein folding and design. The rest of Chapter 6 explores and elaborates these principles and themes.

6.4c Helices and Sheets Make Up the Core of Most Globular Proteins

Globular proteins exist in an enormous variety of three-dimensional structures, but nearly all contain substantial amounts of α -helices and β -sheets folded into a compact structure that is stabilized by both polar and nonpolar interactions. A typical example is *bovine ribonuclease A*, a small protein (12.6 kD, 124 residues) that contains a few short α -helices, a broad section of antiparallel β -sheet, a few β -turns, and several peptide segments without defined secondary structure (Figure 6.17). The space between the helices and sheets in the protein interior is filled efficiently and tightly with mostly hydrophobic amino acid side chains.

Critical Developments in Biochemistry

The Protein Data Bank (PDB)

The Protein Data Bank (PDB, <http://www.wwpdb.org>) is a worldwide archive and repository for information about the three-dimensional structures of proteins, nucleic acids, and complex molecular assemblies. Established in 1971 with just seven structures, the PDB has grown exponentially to contain more than 200,000 entries, with more than 10,000 deposited each year. The Research Collaboratory for Structural Bioinformatics at <http://www.rcsb.org> operates the U.S. data center for the global PDB archive and makes PDB data available at no charge for students and researchers.

Each structure archived in the PDB receives a four-character identifier known as the PDB id. Each PDB file contains information about how the structure was determined, the atoms in each protein or nucleic acid, and their three-dimensional locations

in space as well as the accuracy of the data. A typical PDB file includes a large header section of text that summarizes the protein, citation information, and the details of the structure solution, followed by the sequence and a long list of the atoms and their coordinates. (The PDB file for bovine pancreatic ribonuclease (Figure 6.17, PDB id = 1FS3) is 47 pages long, with the coordinates of 1067 atoms.)

Every macromolecular structure in this text includes the PDB id in the figure legend, so that instructors and students can download and study the structure using any of the freely available software packages for this purpose, including PyMol at <https://pymol.org>, JSmol at <https://sourceforge.net/projects/jsmoll>, and ICM Browser at http://www.molsoft.com/licm_browser.html.

Figure 6.17 The three-dimensional structure of bovine ribonuclease A (PDB id = 1FS3). (a) Ribbon diagram; (b) space-filling model.

Most polar side chains in ribonuclease face the outside of the protein structure and interact with solvent water. With its hydrophobic core and a hydrophilic surface, ribonuclease illustrates the typical properties of many folded globular proteins.

The helices and sheets that make up the core of most globular proteins probably represent the starting point for protein folding. Thus, the folding of a globular protein, in its simplest conception, could be viewed reasonably as the aggregation of multiple elements of secondary structure. Most peptide segments that form helices, sheets, or beta turns in proteins are mostly disordered in small model peptides that contain those amino acid sequences. Thus, hydrophobic interactions and other noncovalent interactions with the rest of the protein must stabilize these relatively unstable helices, sheets, and turns in the folded protein.

The cores of most globular and membrane proteins consist almost entirely of α -helices and β -sheets. The reason is that the highly polar N—H and C=O moieties of the peptide backbone must be neutralized in the hydrophobic core of the protein. The extensively H-bonded nature of α -helices and β -sheets is ideal for this purpose, and these structures effectively stabilize the polar groups of the peptide backbone in the protein core. Hydrogen bonds in the nonpolar core of globular proteins are typically 5–6 kJ/mole stronger than those on the protein surface.

Whereas the interior of a globular protein is composed of conserved sheets and helices, the surface of a globular protein is different in several ways. Typically, much of the protein surface is composed of the loops and tight turns that connect the helices and sheets of the protein core, although helices and sheets may also be found on the surface. The result is that the surface of a globular protein is often a complex landscape of different structural elements. These complex surface structures can interact in certain cases with small molecules or even large proteins that have complementary structure or charge (Figure 6.18). These regions of complementary, recognizable structure are formed typically from the peptide segments that connect elements of secondary structure. They are the basis for enzyme–substrate interactions, protein–protein associations in cell signaling pathways, antigen–antibody interactions, and more.

The segments of the protein that are neither helix, sheet, nor turn have traditionally been referred to as *coil* or *random coil*. Both of these terms are misleading. Most of these *loop* segments are neither coiled nor random in any sense of the words. These structures are every bit as organized and stable as the defined secondary structures. They just don't conform to any frequently recurring pattern. These so-called coil structures are strongly influenced by side-chain interactions with the rest of the protein.

6.4d Water Molecules on the Protein Surface Stabilize the Structure

A globular protein's surface structure is affected by the surrounding water molecules. Many of the polar backbone and side chain groups on the surface of a globular protein make H bonds with solvent water molecules. There are often several such water molecules per amino acid residue, and some are in fixed positions (Figure 6.19). Relatively few water molecules are found inside the protein.

In some globular proteins (Figure 6.20), it is common for one face of an α -helix to be exposed to the water solvent, with the other face toward the hydrophobic interior of the protein. The outward face of such an **amphiphilic helix** consists mainly of polar and charged residues, whereas the inward face contains mostly nonpolar, hydrophobic residues. A good example of such a surface helix is that of residues 153 to 166 of **flavodoxin** from *Anabaena* (Figure 6.20). Note that the **helical wheel presentation** of this helix readily shows that one face contains four hydrophobic residues and that the other is almost entirely polar and charged.

6.4e Packing Considerations

The secondary and tertiary structures of ribonuclease A (Figure 6.17) and other globular proteins illustrate the importance of packing in tertiary structures. Secondary structures pack closely to one another and also intercalate with (insert between) extended polypeptide chains. If the sum of the van der Waals volumes of a protein's constituent

Figure 6.18 The surfaces of proteins are complementary to the molecules they bind. PEP carboxykinase (shown here, PDB id = 1K3D) is an enzyme from the metabolic pathway that synthesizes glucose (gluconeogenesis). In the so-called active site (yellow) of this enzyme, catalysis depends on complementary binding of substrates. Shown in this image are ADP (brown), a Mg^{2+} ion (blue), and AlF_3^- (a phosphate analog, in green, above the Mg^{2+}).

Figure 6.19 The surfaces of proteins are ideally suited to form multiple H bonds with water molecules. Shown here are waters (blue and white) associated with actinidin, an enzyme from kiwi fruit that cleaves polypeptide chains at arginine residues (PDB id = 2ACT). The polar backbone atoms and side chain groups on the surface of actinidin are extensively H-bonded with water.

Figure 6.20 The helical wheel presentation can reveal the polar or nonpolar character of α -helices. If the helix is viewed end on, and the residues are numbered with residue 1 closest to the viewer, it is easy to see how polar and nonpolar residues are distributed to form a wheel. The α -helix consisting of residues 153–166 (red) in flavodoxin from *Anabaena* is a surface helix and is amphipathic (PDB id = 1RCF).

Human Biochemistry

Collagen-Related Diseases

Collagen provides an ideal case study of the molecular basis of physiology and disease. For example, the nature and extent of collagen crosslinking depends on the age and function of the tissue. Collagen from young animals is predominantly uncrosslinked and can be extracted in soluble form, whereas collagen from older animals is highly crosslinked and thus insoluble. The loss of flexibility of joints with aging is probably due in part to increased crosslinking of collagen.

Several serious and debilitating diseases involving collagen abnormalities are known. Lathyrism occurs in animals due to the regular consumption of seeds of *Lathyrus odoratus*, the sweet pea, and involves weakening and abnormalities in blood vessels, joints, and bones. These conditions are caused by **β -aminopropionitrile**, which covalently inactivates lysyl oxidase, preventing intramolecular crosslinking of collagen and causing abnormalities in joints, bones, and blood vessels.

β -Aminopropionitrile

Scurvy results from a dietary vitamin C deficiency and involves the inability to form collagen fibrils properly. This is the result of reduced activity of prolyl hydroxylase, which is vitamin C dependent, as previously noted. Scurvy leads to lesions in the skin and blood vessels, and in its advanced stages, it can lead to grotesque disfigurement and eventual death. Although rare in the modern world, it was a disease well known to sea-faring explorers in earlier times who did not appreciate the importance of fresh fruits and vegetables in the diet.

A number of rare genetic diseases involve collagen abnormalities, including *Marfan syndrome* and the *Ehlers–Danlos syndromes*, which result in hyperextensible joints and skin. The formation of *atherosclerotic plaques*, which cause arterial blockages in advanced stages, is due in part to the abnormal formation of collagenous structures in blood vessels.

amino acids is divided by the volume occupied by the protein, packing densities of 0.72 to 0.77 are typically obtained. These packing densities are similar to those of a collection of solid spheres. This means that even with close packing, approximately 25% of the total volume of a protein is not occupied by protein atoms. Nearly all of this space is in the form of very small cavities. Cavities the size of water molecules or larger do occasionally occur, but they make up only a small fraction of the total protein volume. It is likely that such cavities provide flexibility for proteins and facilitate conformation changes and a wide range of protein dynamics.

Figure 6.21 TonEBP is a DNA-binding protein consisting of two distinct domains. The N-terminal domain is shown here on the right, with DNA (*orange*) in the middle, and the C-terminal domain on the left (PDB id = 1IMH).

6.4f Protein Domains Are Nature's Modular Strategy for Protein Design

Proteins composed of about 250 amino acids or less often have a simple, compact globular shape. However, larger proteins are usually made up of two or more recognizable and distinct structures, termed **domains** or **modules**—compact, folded protein structures that are usually stable by themselves in aqueous solution. Figure 6.21 shows a two-domain DNA-binding protein, TonEBP, in which the two distinct domains are joined by a short segment of the peptide chain. Most domains consist of a single continuous portion of the protein sequence, but in some proteins the domain sequence is interrupted by a sequence belonging to some other part of the protein that may even form a separate domain (Figure 6.22). In either case, typical domain structures consist of hydrophobic cores with hydrophilic surfaces (as was the case for ribonuclease; Figure 6.17). Importantly, individual domains often possess unique functional behaviors (for example, the ability to bind a particular ligand with high affinity and specificity), and an individual domain from a larger protein often expresses its unique function within the larger protein in which it is found. Multidomain proteins typically possess the sum total of functional properties and behaviors of their constituent domains.

It is likely that proteins consisting of multiple domains (and thus multiple functions) evolved by the fusion of genes that once coded for separate proteins. This would require gene duplication to be common in nature, and analysis of completed genomes has confirmed that approximately 90% of domains in eukaryotes have been duplicated. Thus, the protein domain is a fundamental unit in evolution. Many proteins have been assembled by duplicating domains and then combining them in different ways. Many proteins are assemblies constructed from several individual domains, and some proteins contain multiple copies of the same domain. Figure 6.23 shows the tertiary structures of nine domains that are frequently duplicated, and Figure 6.24 presents several proteins that contain multiple copies of one or more of these domains.

6.4g Denaturation Leads to Loss of Protein Structure and Function

Whereas the primary structure of proteins arises from covalent bonds, the secondary, tertiary, and quaternary levels of protein structure are maintained by weak, noncovalent forces. The environment of a living cell is exquisitely suited to maintain these weak forces and to preserve the structures of its many proteins. However, a variety of external stresses—for example, heat or chemical treatment—can disrupt these weak forces in a process termed **denaturation**—the loss of protein structure and function.

Figure 6.22 Malonyl CoA:ACP transacylase (PDB id = 1NM2) is a metabolic enzyme consisting of two subdomains. The large subdomain (*blue*) includes residues 1–132 and 198–316 and consists of a β -sheet surrounded by 12 α -helices. The small subdomain (*gold* = residues 133–197) consists of a four-stranded antiparallel β -sheet and two α -helices.

Human Biochemistry

Domain-Based Engineering of Proteins Forms the Basis of a Novel Cancer Treatment

The rapidly developing field of *synthetic biology* aims to design and create novel biological molecules, processes, and systems for useful purposes. An experimental therapy for acute lymphoblastic leukemia (ALL) illustrates this goal. The patient's own T-cells (one type of immune system cell) are extracted (see figure) and then genetically engineered, using a disabled virus, to express a chimeric antigen receptor (CAR) with a target-binding domain that binds to the B-cell antigen CD19. These engineered T-cells are able to recognize and kill B-cells in the patient that display the CD19 protein. This therapy works because ALL affects B-cells, and destruction of B-cells in many cases overcomes the disease.

The genetic material inserted by the viral vectors has been engineered to encode several different protein domains: a monoclonal antibody domain (the target-binding domain) and two (or more) signaling domains (which promote enhanced proliferation, cytotoxicity, and persistence of the T-cells in the treated patient). Also required are a linking domain and a transmembrane domain, for a total of five or more protein domains! Collectively, the domains

constitute CARs. The target-binding domain of the CAR is extracellular; the signaling domains are intracellular.

In clinical trials involving severe cases of ALL, nearly two-thirds of patients receiving CAR T-cell therapy have remained in complete remission 6 months after being treated. Many of these are still in remission more than a year after treatment.

Ovalbumin monomer

Figure 6.25 The proteins of egg white are denatured (as evidenced by their precipitation and aggregation) during cooking. More than half of the protein in egg whites is ovalbumin. (Ovalbumin PDB id = 1OVA)

An everyday example is the denaturation of the protein ovalbumin during the cooking of an egg (Figure 6.25). About 10% of the mass of an egg white is protein, and 54% of that is ovalbumin. When a chicken egg is cracked open, the egg white is a nearly transparent, viscous fluid. Cooking turns this fluid to a solid, white mass. The egg white proteins have unfolded and have precipitated out of solution, and the unfolded proteins have aggregated into a solid mass.

As a typical protein solution is heated slowly, the protein remains in its native state until it approaches a characteristic melting temperature, T_m . As the solution is heated further, the protein denatures over a narrow range of temperatures around T_m (Figure 6.26). Denaturation over a very small temperature range such as this is evidence of a **two-state transition** between the native and the unfolded states of the protein, and this implies that unfolding is an all-or-none process. When weak forces are disrupted in one part of the protein, the entire structure breaks down.

Most proteins can also be denatured below the transition temperature by a variety of chemical agents, including acid or base, organic solvents, detergents, and particular denaturing solutes. Guanidine hydrochloride and urea are examples of the latter (Figure 6.27). Denaturation in all these cases involves disruption of the weak forces that stabilize proteins. Covalent bonds are not affected. Acids and bases cause protonation and deprotonation of dissociable groups on the protein, altering ionic interactions and hydrogen bonds. Organic solvents and detergents disrupt hydrophobic interactions that bury non-polar groups in the protein interior. The effects of guanidine hydrochloride and urea are

Figure 6.26 Proteins can be denatured by heat, with commensurate loss of function. Ribonuclease A (blue, open circle) and ribonuclease B (red, closed circle) lose activity above about 55°C. These two enzymes share identical protein structures, but ribonuclease B possesses a carbohydrate chain attached to Asn³⁴. (Adapted from Arnold, U., and Ulbrich-Hofmann, R., 1997. Kinetic and thermodynamic thermal stabilities of ribonuclease A and ribonuclease B. *Biochemistry* **36**:2166–2172.)

Figure 6.27 Proteins can be denatured by high concentrations of guanidine-HCl or urea. The denaturation of chymotrypsin in guanidine-HCl (GdmCl) is plotted here. (Adapted from Fersht, A., 1999. *Structure and Mechanism in Protein Science*. New York: W. H. Freeman.)

more complex. These agents denature proteins by both direct effects (binding to hydrophilic groups on the protein) and indirect effects (altering the structure and dynamics of the water solvent). Also, both guanidine hydrochloride and urea are good H-bond donors and acceptors.

6.4h Anfinsen's Classic Experiment Proved That Sequence Determines Structure

What chemical forces drive protein folding? As noted earlier (Section 6.2), all the information needed to fold a polypeptide into its physiological structure is contained in the amino acid sequence. This simple but profound truth of protein structure was confirmed in the 1950s by the elegant studies of denaturation and renaturation of proteins by Christian Anfinsen and his co-workers at the National Institutes of Health. For their pivotal studies, they chose the small enzyme ribonuclease A from bovine pancreas, a protein with 124 residues and four disulfide bonds (Figures 6.17 and 6.28). (Ribonuclease cleaves chains of ribonucleic acid. Only ribonuclease in its native structure possesses enzyme activity, so loss of activity in a denaturation experiment was proof of loss of structure.) They treated solutions of ribonuclease with a combination of urea, which unfolded the protein, and mercaptoethanol, which reduced the disulfide bridges. This treatment destroyed all enzymatic activity of ribonuclease.

Anfinsen discovered that removing the mercaptoethanol but not the urea restored only 1% of the enzyme activity. This was attributed to the formation of random disulfide bridges by the still-denatured protein. With eight Cys residues, there are 105 possible ways to make four disulfide bridges; thus, a residual activity of 1% made sense to Anfinsen. (The first Cys to form a disulfide has seven possible partners, the next Cys has five possible partners, the next has three, and the last Cys has only one choice. $7 \times 5 \times 3 \times 1 = 105$). However, if Anfinsen removed mercaptoethanol *and* urea at the same time, the polypeptide was able to fold into its native structure, the correct set of four disulfides reformed, and full enzyme activity was recovered (Figure 6.28). This experiment demonstrated that the information needed for protein folding resided entirely within the amino acid sequence of the protein itself. Many subsequent experiments with a variety of proteins have confirmed this fundamental postulate. For his studies of the relationship of sequence and structure, Anfinsen shared the 1972 Nobel Prize in Chemistry with William H. Stein and Stanford Moore.

6.4i Is There a Single Mechanism for Protein Folding?

Christian Anfinsen's experiments demonstrated that proteins can fold reversibly and also implies that the native structures of at least some proteins are thermodynamically stable states. But the matter of how a given protein achieves such a stable state is a complex one. Cyrus Levinthal pointed out in 1968 that so many conformations are possible for a typical protein that the protein does not have sufficient time to reach its most stable conformational state by sampling all the possible conformations. This argument, termed *Levinthal's paradox*, goes as follows: Consider a protein of 100 amino acids. Assume that there are only two conformational possibilities per amino acid, or $2^{100} = 1.27 \times 10^{30}$ possibilities. Allow 10^{-13} s for the protein to test each conformational possibility in search of the overall energy minimum:

$$(10^{-13} \text{ s})(1.27 \times 10^{30}) = 1.27 \times 10^{17} \text{ s} = 4 \times 10^9 \text{ years}$$

Four billion years is the approximate age of the earth.

Levinthal's paradox led protein chemists to hypothesize that proteins must fold by specific *folding pathways*, and many research efforts have been devoted to the search for these pathways. Several consistent themes have emerged from these studies. Each of them may well play a role in the folding process:

- Secondary structures—helices, sheets, and turns—probably form first.
- Nonpolar residues may aggregate or coalesce in a process termed **hydrophobic collapse**.

A collaboration of computer scientists and biochemists led by David Baker at the University of Washington created *Foldit*, a computer game based on crowdsourcing and distributed computing. Nearly 200,000 *Foldit* players have devoted millions of hours of computer time to solving a variety of protein folding problems. In *Foldit*, players working collaboratively develop a rich assortment of new strategies and algorithms to better understand the folding of globular proteins. *Foldit* can be found at <http://fold.it/portal/>.

(Cooper, S., et al., 2009. Predicting protein structures with a multiplayer online game. *Nature* **466**:756–760; Farley, P. C., 2013. Using the computer Game “Foldit” to entice students to explore external representations of protein structure in a biochemistry course for nonmajors. *Biochemistry and Molecular Biology Education* **41**:56–57.)

Figure 6.28 Ribonuclease can be unfolded by treatment with urea, and β -mercaptoethanol (MCE) cleaves disulfide bonds. If β -mercaptoethanol is then removed (but not urea) under oxidizing conditions, disulfide bonds reform in the still-unfolded protein (one possible hypothetical inactive form is shown). If urea is removed in the presence of a small amount of β -mercaptoethanol with gentle warming, ribonuclease returns to its native structure (with the correct set of disulfide bonds), and full enzymatic activity is restored. This experiment demonstrated that the information required for folding of globular proteins is contained in the primary structure.

- Subsequent steps probably involve formation of long-range interactions between secondary structures or other hydrophobic interactions.
- The folding process may involve one or more intermediate states, including transition states and what have become known as **molten globules**.

The folding of most globular proteins may well involve several of these themes. For example, even in the denatured state, many proteins appear to possess small amounts of **residual structure** due to hydrophobic interactions, with strong interresidue contacts between side chains that are relatively distant in the native protein structure. Such interactions, together with small amounts of secondary structure, may act as sites of **nucleation** for the folding process. A bit further in the folding process, the molten globule is postulated to be a flexible but compact form characterized by significant amounts of secondary structure, virtually no precise tertiary structure, and a loosely packed hydrophobic core. Moreover, it is likely that any one of these themes is more important for some proteins than for others. The process of folding is clearly complex, but sophisticated simulations have already provided reasonable models of

folding (and unfolding) pathways for many proteins (Figure 6.29). One school of thought suggests that for any given protein there may be multiple folding pathways. For these cases, Ken Dill at the University of California, San Francisco has suggested that the folding process can be pictured as a funnel of free energies—an **energy landscape** (Figure 6.30). The rim at the top of the funnel represents the many possible unfolded states for a polypeptide chain, each characterized by high free energy and significant conformational entropy. Polypeptides fall down the wall of the funnel as contacts made between residues establish different folding possibilities. The narrowing of the funnel reflects the smaller number of available states as the protein approaches

CI2

Barnase

Figure 6.29 Computer simulations of folding and unfolding of proteins can reveal possible folding pathways. Molecular dynamics simulations of the unfolding of small proteins such as chymotrypsin inhibitor 2 (CI2) and barnase are presented here on a reversed time scale to show how folding may occur. D = denatured, I = intermediate, TS = transition state, P = physiological. (Adapted from Daggett, V., and Fersht, A. R., 2003. Is there a unifying mechanism for protein folding? *Trends in Biochemical Sciences* **28**:18–25. Figures provided by Alan Fersht and Valerie Daggett.)

Figure 6.30 A model for the steps involved in the folding of globular proteins. The funnel represents a free energy surface or energy landscape for the folding process. The protein folding process is highly cooperative. Rapid and reversible formation of local secondary structures is followed by a slower phase in which establishment of partially folded intermediates leads to the final tertiary structure.

its final state, and bumps or pockets on the funnel walls represent partially stable intermediates in the folding pathway. The most stable (native) folded state of the protein lies at the bottom of the funnel.

6.4j What Is the Thermodynamic Driving Force for Protein Folding?

The free energy change for the folding of a globular protein must be negative if the folded state is more stable than the unfolded state. The free energy change for folding depends, in turn, on changes in enthalpy and entropy for the process:

$$\Delta G = \Delta H - T\Delta S$$

When ΔH , $-T\Delta S$, and ΔG are measured separately for the polar side chains and for the nonpolar side chains of the protein, an important insight is apparent. The enthalpy and entropy changes for polar residues largely cancel each other out, and the ΔG of folding for the polar residues is approximately zero.

To understand the behavior of the nonpolar residues, it is helpful to distinguish the ΔH and $-T\Delta S$ contributions for the polypeptide chain and for the water solvent. Both ΔH and $-T\Delta S$ for the nonpolar residues of the peptide chain are positive and thus make unfavorable contributions to the folding free energy. However, large numbers of water molecules restricted and immobilized around nonpolar residues in the unfolded protein are liberated in the folding process. The burying of nonpolar residues in the folded protein's core produces a dramatic entropy increase for these liberated water molecules. This is just enough to make the overall ΔG for folding negative (and thus favorable). The crucial results:

- The largest contribution to the stability of a folded protein is the entropy change for the water molecules associated with the nonpolar residues.
- The overall free energy change for the folding process is not large, typically -20 to -40 kJ/mol.

6.4k Marginal Stability of the Tertiary Structure Makes Proteins Flexible

A typical folded protein is only marginally stable. The hundreds of van der Waals interactions and hydrogen bonds in a folded structure are compensated and balanced by a dramatic loss of entropy suffered by the polypeptide as it assumes a compact folded structure. Because stability seems important to protein and cellular function, it is tempting to ask what the advantage of *marginal stability* might be. The answer appears to lie in flexibility and motion. All chemical bonds undergo a variety of motions, including vibrations and (for single bonds) rotations. This propensity to move, together with the marginal stability of protein structures, means that the many noncovalent interactions within a protein can be interrupted, broken, and rearranged rapidly.

6.4l Motion in Globular Proteins

Proteins are best viewed as dynamic structures. Most globular proteins oscillate and fluctuate continuously about their average or equilibrium structures (Figure 6.31). This flexibility is essential for a variety of protein functions, including ligand binding, enzyme catalysis, and enzyme regulation, as shown throughout the remainder of this text.

The motions of proteins may be motions of individual atoms, groups of atoms, or even whole sections of the protein. Furthermore, they may arise either from thermal energy or from specific, triggered conformational changes in the protein. **Atomic fluctuations** such as vibrations typically are random, are very fast, and usually occur over small distances, as shown in Table 6.1. These motions arise from the kinetic energy within the protein and are a function of temperature. In the tightly packed interior of the typical protein, atomic movements of an angstrom or less are typical. The closer to the surface of the protein, the more movement can occur, and on the surface atomic movements of several angstroms are possible.

Figure 6.31 Proteins are dynamic structures. The marginal stability of a tertiary structure leads to flexibility and motion in the protein. Determination of structures of proteins (such as the SH3 domain of the α -chain of spectrin, shown here) by nuclear magnetic resonance produces a variety of stable tertiary structures that fit the data. Such structural ensembles provide a glimpse into the range of structures that may be accessible to a flexible, dynamic protein (PDB id = 1M8M).

Table 6.1 Motion and Fluctuations in Proteins

Type of Motion	Spatial Displacement (Å)	Characteristic Time (s)	Source of Energy
Atomic vibrations	0.01–1	10^{-15} – 10^{-11}	Kinetic energy
Collective motions	0.01–5 or more	10^{-12} – 10^{-3}	Kinetic energy
1. Fast: Tyr ring flips; methyl group rotations			
2. Slow: hinge bending between domains			
Triggered conformation changes	0.5–10 or more	10^{-9} – 10^3	Interactions with triggering agent
Proline <i>cis</i> – <i>trans</i> isomerization	3–10	10^1 – 10^4	Kinetic energy or enzyme driven

Adapted from Petsko, G. A., and Ringe, D., 1984. Fluctuations in protein structure from X-ray diffraction. *Annual Review of Biophysics and Bioengineering* 13:331–371.

A class of slower motions, which may extend over larger distances, is **collective motions**. These are movements of a group of atoms covalently linked in such a way that the group moves as a unit. Such a group can range from a few atoms to hundreds of atoms. These motions are of two types: (1) those that occur quickly but infrequently, such as tyrosine ring flips, and (2) those that occur slowly, such as the hinge-bending movement between protein domains. For example, the two antigen-binding domains of immunoglobulins move as relatively rigid units to selectively bind separate antigen molecules. These collective motions also arise from thermal energies in the protein and operate on a timescale of 10^{-12} to 10^{-3} s. It is often important to distinguish the time scale of the motion itself versus the frequency of its occurrence. A tyrosine ring flip takes only a picosecond (1×10^{-12} s), but such flips occur only about once every millisecond (1×10^{-3} s).

Conformational changes involve motions of groups of atoms (individual side chains, for example) or even whole sections of proteins. These motions occur on a time scale of 10^{-9} to 10^3 s, and the distances covered can be as large as 1 nm. These motions may occur in response to specific stimuli or arise from specific interactions within the protein (hydrogen bonding, electrostatic interactions, or ligand binding—see Chapters 13–15).

The *cis*–*trans* isomerization of proline residues in proteins (Figure 6.32) occurs over an even longer time scale—typically 10^1 to 10^4 s. Conversion of even a single proline from its *cis* to its *trans* conformation can alter a protein structure dramatically. Proline *cis*–*trans* isomerizations sometimes act as switches to activate a protein or open a channel across a membrane.

6.4m The Folding Tendencies and Patterns of Globular Proteins

Globular proteins adopt the most stable tertiary structure possible. The polypeptide itself does not usually form simple straight chains. Even in chain segments where helices and sheets are not formed, an extended peptide chain, being composed of L-amino acids, has a tendency to twist slightly in a right-handed direction. As shown in Figure 6.33, this tendency is apparently the basis for the formation of a variety of tertiary structures with a right-handed sense. Principal among these are the right-handed twists in β -sheets and right-handed cross-overs in parallel β -sheets. Right-handed twisted β -sheets are found at the center of a number of proteins (Figure 6.34) and provide an extended, highly stable structural core.

Connections between β -strands are of two types—hairpins and cross-overs. **Hairpins**, as shown in Figure 6.33, connect adjacent antiparallel β -strands. **Cross-overs** are necessary to connect adjacent (or nearly adjacent) parallel β -strands. Nearly

Figure 6.32 The *cis* and *trans* configurations of proline residues in peptide chains are almost equally stable. Proline *cis*–*trans* isomerizations, often occurring over relatively long time scales, can alter protein structure significantly.

Figure 6.33 (a) The natural right-handed twist exhibited by polypeptide chains, and (b) the types of connections between β -strands.

Figure 6.34 Examples of protein domains with different numbers of layers of backbone structure. (a) Cytochrome *c'* with two layers of α -helix. (b) Domain 2 of phosphoglycerate kinase, composed of a β -sheet layer between two layers of helix, three layers overall. (c) An unusual five-layer structure, domain 2 of glycogen phosphorylase, a β -sheet layer sandwiched between four layers of α -helix. (d) The concentric "layers" of β -sheet (inside) and α -helix (outside) in triose phosphate isomerase. Hydrophobic residues are buried between these concentric layers in the same manner as in the planar layers of the other proteins. The hydrophobic layers are shaded yellow. A Deeper Look

Metamorphic Proteins—A Consequence of Dynamism and Marginal Stability

As our knowledge evolves, we find that our understanding of protein structure is like the story of the inebriated man wandering under a street lamp one night. A passerby asks what he is doing, and the man answers that he is looking for his keys. When the passerby asks “Where did you lose them?,” the man answers “Down the street a ways.” And when the passerby asks, “Why are you looking here?” the man replies, “There’s more light here!”

(Left) PDB id = 2KDL; (Right) PDB id = 2KDM

Until recently, biochemists have been like the inebriated man. Proteins that have been most amenable to structural studies, those have been the more stable proteins that favor a single conformation. As structural methodologies have evolved, we have come to appreciate that many proteins can exist as an ensemble of structures of more or less similar energies and stabilities. Some of the recent work has been remarkable. For example, it is becoming clear that a few mutations can dramatically change the three-dimensional structure of a protein. Philip Bryan and co-workers have shown that the conversion of *Streptococcus* protein G, a 56-residue protein, from a structure dominated by three α -helices to a structure with four β -strands and an α -helix can occur via a single amino acid substitution—changing residue 45 from Leu to Tyr.

all cross-over structures are right-handed. In many cross-over structures, the cross-over connection itself contains an α -helical segment. This creates a **$\beta\alpha\beta$ -loop**. As shown in Figure 6.33, the strong tendency in nature to form right-handed cross-overs, the wide occurrence of α -helices in the cross-over connection, and the right-handed twists of β -sheets can all be understood as arising from the tendency of an extended polypeptide chain (composed of L-amino acids) to adopt a right-handed twist structure. This is a chiral effect. Proteins composed of D-amino acids would tend to adopt left-handed twist structures.

The second driving force that affects the folding of polypeptide chains is the need to bury the hydrophobic residues of the chain, protecting them from solvent water. From a topological viewpoint, then, all globular proteins must have an “inside” where the hydrophobic core can be arranged and an “outside” toward which the hydrophilic groups must be directed. The sequestration of hydrophobic residues away from water is the dominant force in the arrangement of secondary structures and nonrepetitive peptide segments to form a given tertiary structure. Globular proteins can be classified mainly on the basis of the particular kind of core or backbone structure they use to accomplish this goal. The term *hydrophobic core*, as used here, refers to a region in which hydrophobic side chains cluster together, away from the solvent. *Backbone* refers to the polypeptide backbone itself, excluding the particular side chains. Globular proteins can be pictured as consisting of “layers” of backbone, with hydrophobic core regions between them. More than half of the known globular protein structures have two layers of backbone (separated by one hydrophobic core). Roughly one-third of the known structures are composed of three backbone layers and two hydrophobic cores. There are also a few known four-layer structures and at least one five-layer structure. A few structures are not easily classified in this way, but it is remarkable that most proteins fit into one of these classes. Examples of each are presented in Figure 6.34.

6.4n Proteins Can Be Classified on the Basis of Folding Patterns

The astounding diversity of properties and behaviors in living things can now be explored through the analysis of vast amounts of genomic information. Assessment of sequence and structural data from over 20 million proteins in both protein and genome databases has shown that there is a relatively limited number of structurally distinct domains in proteins. Moreover, most proteins are structurally similar to at least some other proteins, and in many cases are related evolutionarily. Several comprehensive projects have organized the available information in defined hierarchies, or even more complex relationships or levels of protein structure. The Structural Classification of Proteins database (SCOP2, <https://scop.mrc-lmb.cam.ac.uk/>) uses both automated algorithms and manual inspection to describe the structural and evolutionary relationships between all the proteins whose structures are known. All proteins in SCOP2 are described and can be searched by four properties: protein types, structural classes, folding relationships, and evolutionary relationships. **Protein type** includes four groups: soluble, fibrous, membrane, and intrinsically disordered proteins. **Protein structural classes** define the types and arrangements of secondary structure (Figure 6.35) in four broad groups: the **all α proteins** and **all β proteins** (in which the structures are dominated by α -helices and β -sheets, respectively) as well as **α/β proteins** (in which helices and sheets are intermingled) and **$\alpha + \beta$ proteins** (in which α -helical and β -sheet domains are separated for the most part). **Folding relationships** in SCOP2 are based on families, superfamilies, and folds. **Family** groups closely related proteins that show clear evidence of evolutionary origin. **Superfamily** brings together more distantly related protein domains, again based on common evolutionary origin. The **fold** criterion in SCOP2 relates superfamilies on the basis of the global structural features shared by the majority of the proteins. A fold describes the number, arrangement, and connections of secondary structure elements. Fold is an attribute of a superfamily, but the families within superfamilies that have evolved distinct structural features can belong to a different fold.

Although the numbers of unique folds (more than 1500), superfamilies (more than 2600), and families (more than 5600) increase as more genomes are known and analyzed, it has become apparent that *the number of protein domains in nature is large but limited*. How many proteins can we expect to identify and understand someday? The Protein Data Bank curates more than 200,000 structures at present. There are approximately 10^3 to 10^5 genes per organism and approximately 14 million species of living organisms on earth (and this latter number is likely an underestimate). Thus, there may be approximately $(10^3 \times 1.4 \times 10^7)$ or 10^{10} to 10^{12} different proteins in all organisms on earth. Still, this vast number of proteins may well consist of only a couple thousand folds and a few thousand protein families—remarkably small numbers compared to the total number of protein-coding genes (see Table 1.5). It is anticipated that most newly identified proteins will resemble other known proteins and that most structures can be broken into two or more domains, which resemble tertiary structures observed in other proteins.

Figure 6.35 Four major classes of protein structure (as defined in the SCOP database). (a) All α proteins, where α -helices dominate the structure; (b) All β proteins, in which β -sheets are the primary feature; (c) α/β proteins, where α -helices and β -sheets are mixed within a domain; (d) $\alpha + \beta$ proteins, in which α -helical and β -sheet domains are separated to at least some extent.

(a) Same domain type, different functions:

Triose phosphate isomerase

Aldose reductase

Phosphotriesterase

(b) Same function, different structures:

Aspartate aminotransferase

D-amino acid aminotransferase

Figure 6.36 Structure and function are not always correlated closely in proteins. **(a)** Some proteins share similar structural features but carry out quite different functions (triose phosphate isomerase, PDB id = 8TIM; aldose reductase, PDB id = 1ADS; phosphotriesterase, PDB id = 1DPM). **(b)** Proteins with quite different structures can carry out similar functions (yeast aspartate aminotransferase, PDB id = 1YAA; D-amino acid aminotransferase, PDB id = 3DAA).

Among the proteins in the PDB, many domains and folds recur hundreds or even thousands of times, yet conservation of amino acid sequence is much less common. When sequence and structure are both conserved, the evolutionary relationship is stronger.

Because structure depends on sequence, and because function depends on structure, it is tempting to imagine that all proteins of a similar structure should share a common function, but this is not always true. For example, the TIM barrel is a common protein fold consisting of eight α -helices and eight β -strands that alternate along the peptide backbone to form a doughnut-like tertiary structure. The TIM barrel is named for triose phosphate isomerase, an enzyme that interconverts ketone and aldehyde substrates in the breakdown of sugars. However, other TIM barrel proteins carry out very different functions (Figure 6.36a), including the reduction of aldose sugars and hydrolysis of phosphate esters. Moreover, not all proteins of similar function possess similar domains. Both proteins shown in Figure 6.36b catalyze the same reaction, but they bear little structural similarity to each other.

6.4o Molecular Chaperones Are Proteins That Help Other Proteins to Fold

All the information necessary to direct the folding of a polypeptide is contained in its primary structure. On the other hand, the high protein concentration inside cells may adversely affect the folding process because hydrophobic interactions may lead to aggregation of some unfolded or partially folded proteins. Also, it may be necessary to suppress or reverse incorrect or premature folding. A family of proteins, known as **molecular chaperones**, are essential for the correct folding of certain polypeptide chains *in vivo*; for their assembly into oligomers; and for preventing inappropriate liaisons with other proteins during their synthesis, folding, and transport. Many of these proteins

were first identified as **heat shock proteins**, which are induced in cells by elevated temperature or other stress. The most thoroughly studied proteins are **Hsp70**, a 70-kDa heat shock protein, and the so-called **chaperonins**, also known as **Cpn60s** or **Hsp60s**, a class of 60-kDa heat shock proteins. A well-characterized **Hsp60** chaperonin is **GroEL**, an *E. coli* protein that has been shown to affect the folding of several proteins.

6.4p Some Proteins Are Intrinsically Unstructured

Remarkably, many proteins exist and function normally in a partially unfolded state. Such proteins, termed **intrinsically unstructured proteins (IUPs)** or **intrinsically disordered proteins (IDPs)**, do not possess uniform structural properties but are nonetheless essential for basic cellular functions. These proteins are characterized by an almost complete lack of folded structure and an extended conformation with high intramolecular flexibility. Yet they are essential for many basic cellular functions, including protein solubility enhancement, regulation of protein lifetimes via control of proteolysis, and control of protein–protein interactions.

The ordered and disordered domains of a protein (Figure 6.37) may function independently, and regions of a protein can undergo order–disorder transitions. These transitions underlie biological function, and they can be induced by binding of small molecules and/or macromolecular binding partners, or by post-translational modifications. For example, order–disorder transitions modulate DNA–protein interactions. In addition, the assembly of ribosomes (the centers of cellular protein synthesis) depends on order–disorder transitions in ribosomal proteins, essentially all of which have large intrinsically disordered regions.

Intrinsically unstructured proteins are characterized by a unique combination of high net charge and low overall hydrophobicity. Compared with ordered proteins, IUPs have higher levels of E, K, R, G, Q, S, and P, and low amounts of I, L, V, W, F, Y, C, and N. Intrinsically disordered proteins and disordered regions in otherwise structured proteins do not fold primarily because they are rich in polar residues and proline and depleted in hydrophobic residues. The greater the net charge, the more extended an IDP region is.

These features provide a rationale for prediction of regions of disorder from amino acid sequence information, and experimental evidence shows that such predictions are better than 80% accurate. Genomic analysis of disordered proteins indicates that

Figure 6.37 Intrinsically unstructured proteins (IUPs) contact their target proteins over a large surface area. **(a)** p27^{Kip1} (yellow) complexed with cyclin-dependent kinase 2 (Cdk2, blue) and cyclin A (CycA, green). **(b)** The transactivator domain CBD of TCF3 (yellow) bound to β -catenin (blue). **Note:** Part of the β -catenin has been removed for a clear view of the CBD. (From Tompa, P., 2002. Intrinsically unstructured proteins. *Trends in Biochemical Sciences* 27:527–533.) **(c)** Some intrinsically unstructured proteins (in red and yellow) bind to their targets by wrapping around them. Shown here: SNAP-25 wrapped around BoNT/A, (Adapted from Figure 1 in Tompa, P., 2002. Intrinsically unstructured proteins. *Trends in Biological Sciences* 27:527–533.)

the proportion of the genome encoding IUPs and proteins with substantial regions of disorder tends to increase with the complexity of organisms. Thus, predictive analysis of whole genomes indicates that 2% of archaeal and 4.2% of bacterial proteins probably contain long regions of disorder. On the other hand, 25% to 30% of eukaryotic proteins are mostly disordered, and more than half of eukaryotic proteins have long regions of disorder. Depending on which predictor is used, the human proteome is estimated to have between 35% and 50% disordered residues. More than 70% of human signaling proteins have long disordered regions.

A given IDP or IDP region can change its shape in order to bind to multiple different partners—a phenomenon termed **one-to-many binding**. An example of such behavior is the tumor suppressor protein p53. This 53 kDa protein consists of an N-terminal disordered domain of 93 residues, a central DNA-binding domain of 200 residues, and a C-terminal disordered domain of about 100 residues. The N-terminal domain apparently binds to more than 40 different protein partners, and the C-terminal domain binds to an even larger number of target proteins (Figure 6.38). This large number of interactions is consistent with involvement of p53 in multiple signaling and regulatory pathways in cells and also suggests a complicated competition between the various protein targets for p53. Indeed, p53 is a crucial transcription factor whose activity is modulated by a wide spectrum of signals that affect cell proliferation and genome integrity.

The prevalence of disordered segments in proteins may reflect two different cellular needs. First, disordered proteins are more malleable and thus can adapt their structures to bind to multiple ligands, including other proteins. Each such interaction could provide a different function in the cell. Second, compared with compact, folded proteins, disordered segments in proteins appear to be able to form larger intermolecular interfaces to which ligands, such as other proteins, could bind (Figure 6.37). Folded

Figure 6.38 Molecular disorder of tumor suppressor protein p53. The sequence consists of a 93-residue, mostly disordered N-terminal segment, a central, DNA-binding domain of 200 residues, and a mostly disordered C-terminal segment of about a hundred residues. Gray arrows indicate binding interactions of each domain with partner proteins. Binding partners of the N-terminal domain include (clockwise from lower right) high-mobility group protein B1 (PDB id = 2LY4), Taz2 domain of p300 (PDB id = 2K8F), nuclear coactivator-binding domain of p300 (PDB id = 2L14), MDM2 (PDB id = 1YCR), N terminus of replication protein A (PDB id = 2B3G), and PH domain of RNA polymerase II transcription factor B subunit 1 (PDB id = 2GS0). Eight partners of the C terminal domain are (clockwise from upper left) histone acetyltransferase domain of *Tetrahymena* general control nonderepressor 5 (PDB id = 1Q2D), SET9 (PDB id = 1XQH), CDK2/cyclin A (PDB id = 1H26), Sir2 (PDB id = 1MA3), bromodomain of CBP (PDB id = 1JSP), S100B($\beta\beta$) (PDB id = 1DT7), Tudor2 domain of PHF20 (PDB id = 2LDM), and p53 homotetramerization (PDB id = 3SAK). (Adapted from Oldfield, C. J. and Dunker, K. E., 2014. Intrinsically Disordered Proteins and Intrinsically Disordered Protein Regions. *Annual Review of Biochemistry* 83:553–584.)

proteins might have to be two to three times larger to produce the binding surface possible with a disordered protein. Larger proteins would increase cellular crowding or could increase cell size by 15% to 30%. The flexibility of disordered proteins may thus reduce protein, genome, and cell sizes.

6.4q Artificial Intelligence Algorithms Predict Protein Structures Accurately

AlphaFold is an artificial intelligence program developed by Alphabet/Google's DeepMind subsidiary that can predict three-dimensional structures of proteins with high accuracy. Millions of structures of proteins from the human proteome and other key proteins of interest have been generated, based only on the primary structures of these proteins. The AlphaFold2 software is open-source and the AlphaFold Protein Structure Database (<https://alphafold.ebi.ac.uk/>) provides open access to protein models generated with this software.

Critical Developments in Biochemistry

NMR and Cryo-EM – Revolutionary Methods that Probe Protein Structure and Dynamics

Nuclear magnetic resonance (NMR) spectroscopy is particularly suited for the study of macromolecular structure and dynamics in solution. Nuclei with an odd number of protons and/or neutrons possess a nuclear spin angular momentum, termed nuclear spin, and behave as magnetic dipoles. Certain of these nuclei (^1H , ^{13}C , ^{15}N , ^{19}F , ^{31}P), when placed in a strong magnetic field, can absorb short pulses ($\sim 10\text{--}20\ \mu\text{s}$) of electromagnetic energy in the radio frequency range. The absorption spectrum yields information about chemical environment, and the relaxation from high energy states provides information about dynamics in the molecule. ^1H , ^{13}C , and ^{15}N are all suitable for NMR studies of proteins, but the natural abundance of ^{13}C (1%) and ^{15}N (0.4%) are so low that proteins must be expressed in bacteria grown in ^{13}C - and ^{15}N -enriched media, to achieve the highest possible sensitivity in NMR experiments.

Two-dimensional NMR can reveal interactions between two nuclei (proton-proton, proton-carbon, or proton-nitrogen) in a protein, in two ways. Couplings of nuclear spins through covalent bonds in total correlation spectroscopy (TOCSY) or heteronuclear single quantum coherence (HSQC) spectroscopy provides local structure information, and spin-spin coupling through space (the nuclear Overhauser effect, or NOE) identifies pairs of nuclei that are close in space but may be distant in the protein sequence in NOESY experiments.

The real advantage of NMR, over other structural measurements, is in studies of dynamics in proteins. Many proteins are ensembles of interchanging states in solution, and the NMR spectrum is a population-weighted average over this ensemble. NMR

Figure 1 (a) ^1H - ^{15}N HSQC spectra of the TAZ1 domain of CREB-binding protein (CBP) (a human transcription factor) alone (black) and in complex with two intrinsically disordered proteins, HIF-1 α (gold) and CITED2 (blue). Assignments are shown for selected crosspeaks. The tryptophan indole resonance is shown as an inset in the bottom left corner. (Adapted from Dyson, H. J. and Wright, P. E., Perspective: the essential role of NMR in the discovery and characterization of intrinsically disordered proteins. *J. Biomol. NMR* 73:651–659.) (b) NMR structure of TAZ1 in complex with HIF-1 α .

provides quantitative information about ensembles that is not available from any other technique.

Moreover, NMR parameters are now used routinely for characterization of intrinsically disordered proteins (IDPs, Figure 1) and form the basis for quantitative modeling of the conformational ensemble and energy landscape. NMR can be used to characterize the conformation and dynamics of the free and bound states of the IDP, the binding process, and the binding affinity. NMR relaxation data can be used to characterize the kinetics and mechanism of coupled folding and binding processes. NMR offers a valuable technology for characterization of conformational ensembles of proteins, their dynamics, and their complexes with other biomolecules.

Three-dimensional electron microscopy, more commonly known as **cryo-EM**, can determine three-dimensional structures of large macromolecules. The methods of cryo-EM—single particle analysis, electron crystallography and electron tomography—all involve scattering of a coherent electron beam to image the biomolecule which has been flash-frozen into thin disks of ice using liquid ethane, to prevent the formation of crystalline ice. After the electron beam passes through the sample, a system of lenses converts the scattered signal into a magnified image recorded on a detector. Computerized signal processing then generates the three-dimensional structure of the sample. In **single particle** methods, many thousands of different single particles are preserved in a thin layer of non-crystalline

ice. If the imaged particles show the molecule in many different orientations, computational methods can produce a three-dimensional mass density map, and an atomic model can be fit to the map. In **electron crystallography**, diffraction of electrons from two-dimensional or three-dimensional crystals can be used to determine three-dimensional structure, in much the same way as X-ray crystallography. In electron tomography, the electron beam is passed through the sample at a series of different tilt angles, and the images obtained from multiples copies of the macromolecule are averaged by computer.

Recent technical developments, including improvements in sample preparation and preservation, improved detectors and electron optics, faster computers and improved data processing software, have advanced the power and resolution of cryo-EM dramatically (Figure 2). Both single particle cryo-EM and electron diffraction methods have now achieved resolution (1.2–1.7 Å) rivaling X-ray crystallography. For very large macromolecular assemblies, cryo-EM data can be combined with data from NMR spectroscopy, X-ray crystallography, mass spectrometry and computational techniques to elucidate structural details. Such **integrative methods (IM)** have been applied to the structures of ribosomes, muscle structures, and tRNA complexes, among others. PDB-Dev at <https://pdb-dev.wwpdb.org> is a prototype archiving system for structural models obtained using integrative or hybrid modeling.

Figure 2 Development of mRNA vaccines for the novel coronavirus, SARS-CoV-2, benefitted from years of work on other virus vaccines, including cryo-EM studies of virus spike protein structures. Coronavirus particles introduced into a host must fuse with (bind to) receptor proteins on the host's cells. Prior to this binding, the spike protein is in its prefusion conformation, with a portion of its structure in the down position (a, PDB id = 6VXX). This form cannot bind to host receptor proteins. A second prefusion state, referred to as the up conformation (b, PDB id = 6VSB) can bind to those receptors. An mRNA vaccine must produce spike proteins in the host that mimic the up prefusion conformation, to raise effective antibodies to the virus itself. Barney Graham and Jason McLellan produced a mutant spike protein with two added prolines that locked the protein into the up prefusion state. The mRNA for that "2P" mutant is the basis for both the Pfizer and Moderna COVID-19 vaccines. (Wrapp, D. Wang, N., Corbett, K. S. et al., 2020. Cryo-EM structure of the 2019-nCoV spike in the prefusion conformation. *Science* 367:1260–1263.)

6.5 | How Do Protein Subunits Interact at the Quaternary Level of Protein Structure?

Many proteins exist in nature as **oligomers**, complexes composed of (often symmetric) noncovalent assemblies of two or more monomer subunits. In fact, subunit association is a common feature of macromolecular organization in biology. Most intracellular enzymes are oligomeric and may be composed either of a single type of monomer subunit (*homomultimers*) or of several different kinds of subunits

Figure 6.39 The quaternary structure of liver alcohol dehydrogenase. Within each subunit is a six-stranded parallel sheet. Between the two subunits is a two-stranded antiparallel sheet (PDB id = 1CDO).

(heteromultimers). Liver alcohol dehydrogenase is a homodimer, a protein composed of identical subunits (Figure 6.39). Alcohol consumed in a beer or mixed drink is oxidized in the liver by alcohol dehydrogenase. Hormonal signals modulate blood sugar levels by controlling the activity of glycogen phosphorylase, another homodimeric enzyme. Oxygen is carried in the blood by hemoglobin, which contains two each of two different subunits (*heterotetramer*). A counterpoint to these small clusters is made by the proteins that form large *polymeric* aggregates. Proteins are synthesized on large complexes of many protein units and several RNA molecules called *ribosomes*. Muscle contraction depends on large polymer clusters of the protein myosin sliding along filamentous polymers of another protein, actin. The way in which

Human Biochemistry

Diseases of Protein Folding

A number of human diseases are linked to abnormalities of protein folding. Protein misfolding may cause disease by a variety of mechanisms. For example, misfolding may result in loss of function and the onset of disease. The following table summarizes several other mechanisms and provides an example of each.

Disease	Affected Protein	Mechanism
Alzheimer’s disease	β -Amyloid peptide (derived from amyloid precursor protein)	Misfolded β -amyloid peptide accumulates in human neural tissue, forming deposits known as neuritic plaques.
Familial amyloidotic polyneuropathy	Transthyretin	Aggregation of unfolded proteins. Nerves and other organs are damaged by deposits of insoluble protein products.
Cancer	p53	p53 prevents cells with damaged DNA from dividing. One class of p53 mutations leads to misfolding; the misfolded protein is unstable and is destroyed.
Creutzfeldt–Jakob disease (human equivalent of mad cow disease)	Prion	Prion protein with an altered conformation (PrP ^{Sc}) may seed conformational transitions in normal PrP (PrP ^C) molecules.
Hereditary emphysema	α_1 -Antitrypsin	Mutated forms of this protein fold slowly, allowing its target, elastase, to destroy lung tissue.
Cystic fibrosis	CFTR (cystic fibrosis transmembrane conductance regulator)	Folding intermediates of mutant CFTR forms don’t dissociate freely from chaperones, preventing the CFTR from reaching its destination in the membrane.

Human Biochemistry

Structural Genomics

The prodigious advances in genome sequencing in recent years, together with advances in techniques for protein structure determination, not only have provided much new information for biochemists but have also spawned a new field of investigation—**structural genomics**, the large-scale analysis of protein structures and functions based on gene sequences. The scale of this new endeavor is daunting: hundreds of thousands of gene sequences are rapidly being determined, and current estimates suggest that there are probably fewer than 10,000 distinct and stable polypeptide folding patterns in nature. The feasibility of large-scale, high-throughput structure determination programs is being explored in a variety of pilot studies in Europe, Asia, and North America. These efforts seek to add 20,000 or more new protein structures to our collected knowledge in the near future; from this wealth of new information, it should be possible to predict and determine new structures from sequence information alone. This effort will be vastly more complex and more expensive than the Human Genome Project. It presently costs about \$100,000 to determine the structure of the typical globular protein,

and one of the goals of structural genomics is to reduce this number to \$20,000 or less. Advances in techniques for protein crystallization, X-ray diffraction, and NMR spectroscopy, the three techniques essential to protein structure determination, will be needed to reach this goal in the near future.

The payoffs anticipated from structural genomics are substantial. Access to large amounts of new three-dimensional structural information should accelerate the development of new families of drugs. The ability to scan databases of chemical entities for activities against drug targets will be enhanced if large numbers of new protein structures are available, especially if complexes of drugs and target proteins can be obtained or predicted. The impact of structural genomics will also extend, however, to **functional genomics**—the study of the functional relationships of genomic content—which will enable the comparison of the composite functions of whole genomes, leading eventually to a complete biochemical and mechanistic understanding of all organisms, including humans.

separate folded monomeric protein subunits associate to form the oligomeric protein constitutes the **quaternary structure** of that protein. Table 6.2 lists several proteins and their subunit compositions (see also Table 4.2). Proteins with two to four subunits predominate in nature, but many cases of higher numbers exist.

The subunits of an oligomeric protein typically fold independently and then interact with other subunits. The surfaces at which subunits interact are similar in nature to the interiors of the individual subunits—closely packed with both polar and hydrophobic interactions. Interacting surfaces must therefore possess *complementary* arrangements of polar and hydrophobic groups.

6.5a There Is Symmetry in Quaternary Structures

Many multimeric proteins are symmetric arrangements of asymmetric objects (the monomer subunits). All of the polypeptide's α -carbons are asymmetric, and the polypeptide nearly always folds to form a low-symmetry structure. Thus, protein subunits do not have mirror reflection planes, points, or axes of inversion. The only symmetry operation possible for protein subunits is a rotation. The most common symmetries observed for multisubunit proteins are cyclic symmetry and dihedral symmetry. In **cyclic symmetry**, the subunits are arranged around a single rotation axis, as shown in Figure 6.40. If there are two subunits, the axis is referred to as a *twofold rotation axis*. Rotating the quaternary structure 180° about this axis gives a structure identical to the original one. With three subunits arranged about a threefold rotation axis, a rotation of 120° about that axis gives an identical structure. **Dihedral symmetry** occurs when a structure possesses at least one twofold rotation axis perpendicular to another *n*-fold rotation axis. This type of subunit arrangement (Figure 6.40) occurs in annexin XII (where *n* = 3).

6.5b Quaternary Association Is Driven by Weak Forces

Weak forces stabilize quaternary structures. Typical dissociation constants for simple two-subunit associations range from 10^{-8} to 10^{-16} *M*. These values correspond to free energies of association of about 50 to 100 kJ/mol at 37° C. Dimerization of subunits is accompanied by both favorable and unfavorable energy changes. The favorable interactions include van der Waals interactions, hydrogen bonds, ionic bonds, and hydrophobic interactions. However, considerable entropy loss occurs when subunits interact. When two subunits move as one, three translational degrees of freedom (that

Table 6.2 Aggregation Symmetries of Globular Proteins

Figure 6.40 Multimeric proteins are symmetric arrangements of asymmetric objects. A variety of symmetries is displayed in these multimeric structures.

is, the ability to move freely in three dimensions) are lost for one subunit because it is constrained to move with the other one. In addition, many residues at the subunit interface, which were previously free to move on the protein surface, now have their movements restricted by the subunit association. This unfavorable energy of association is in the range of 80 to 120 kJ/mol for temperatures of 25° to 37°C. Thus, to achieve stability, the dimerization of two subunits must involve approximately 130 to 220 kJ/mol of favorable interactions.¹ Van der Waals interactions at protein interfaces are numerous, often running to several hundred for a typical monomer–monomer association. This would account for about 150 to 200 kJ/mol of favorable free energy of association. However, when solvent is removed from the protein surface to form the subunit–subunit contacts, nearly as many van der Waals associations are lost as are made. One subunit is simply trading water molecules for residues in the other subunit. As a result, the energy of subunit association due to van der Waals interactions actually contributes little to the stability of the dimer. Hydrophobic interactions at the subunit–subunit interface, however, are generally very favorable. For many proteins, the subunit association process effectively buries as much as 20 nm² of surface area previously exposed to solvent, resulting in as much as 100 to 200 kJ/mol of favorable hydrophobic interactions. Together with whatever polar interactions occur at the protein–protein interface, this is sufficient to account for the observed stabilization that occurs when two protein subunits associate.

An additional and important factor contributing to the stability of subunit associations for some proteins is the formation of disulfide bonds between different subunits. All antibodies are $\alpha_2\beta_2$ -tetramers composed of two heavy chains (53 to 75 kDa) and two light chains (23 kDa). In addition to *intrasubunit* disulfide bonds (four per heavy chain, two per light chain), two *intersubunit* disulfide bridges hold the two heavy chains together and a disulfide bridge links each of the two light chains to a heavy chain (Figure 6.41).

6.5c Open Quaternary Structures Can Polymerize

All of the quaternary structures we have considered to this point have been **closed** structures, with a limited capacity to associate. (“Closed” here means that additional subunits cannot be bound.) Many proteins in nature associate to form **open** heterologous structures, which can polymerize more or less indefinitely, creating structures that are both esthetically attractive and functionally important to the cells or tissue in which they exist. One such protein is **tubulin**, the $\alpha\beta$ -dimeric protein that polymerizes into long, tubular structures that are the structural basis of cilia, flagella, and the cytoskeletal matrix. The microtubule thus formed (Figure 6.42) consist of 13 parallel filaments arising from end-to-end aggregation of the tubulin dimers. Human immunodeficiency virus, HIV, the causative agent of AIDS is enveloped by a spherical shell composed of hundreds of coat protein subunits, a large-scale, but closed, quaternary association.

6.5d There Are Structural and Functional Advantages to Quaternary Association

There are several important consequences when protein subunits associate in oligomeric structures.

Stability One general benefit of subunit association is a favorable reduction of the protein’s surface-to-volume ratio. The surface-to-volume ratio becomes smaller as the radius of any particle or object becomes larger. (This is because surface area is a function of

¹For example, 130 kJ/mol of favorable interaction minus 80 kJ/mol of unfavorable interaction equals a net free energy of association of 50 kJ/mol.

Figure 6.42 The structure of a typical microtubule, showing the arrangement of the α - and β -monomers of the tubulin dimer.

Figure 6.41 Schematic drawing of an immunoglobulin molecule, showing the intermolecular and intramolecular disulfide bonds. Two identical L chains are joined with two identical H chains. Each L chain is held to an H chain via an interchain disulfide bond. The variable regions of the four polypeptides lie at the ends of the arms of the Y-shaped molecule. These regions are responsible for the antigen recognition function of antibody molecules. For purposes of illustration, some features are shown on only one or the other L chain or H chain, but all features are common to both chains.

Human Biochemistry

Faster-Acting Insulin: Genetic Engineering Solves a Quaternary Structure Problem

Insulin is a peptide hormone secreted by the pancreas that regulates glucose metabolism in the body. Insufficient production of insulin or failure of insulin to stimulate target sites in liver, muscle, and adipose tissue leads to the serious metabolic disorder known as *diabetes mellitus*. Diabetes afflicts millions of people worldwide. Diabetic individuals typically exhibit high levels of glucose in the blood, but insulin injection therapy allows these individuals to maintain normal levels of blood glucose.

Insulin is composed of two peptide chains covalently linked by disulfide bonds (see Figure 5.8). This monomer of insulin is the active form that binds to receptors in target cells. However, in solution, insulin spontaneously forms dimers, which themselves aggregate to form hexamers. The surface of the insulin molecule that self-associates to form hexamers is also the surface that binds to insulin receptors in target cells. Thus, hexamers of insulin are inactive.

Insulin released from the pancreas is monomeric and acts rapidly at target tissues. However, when insulin is administered by injection to a diabetic patient, the insulin hexamers dissociate slowly and the patient's blood glucose levels typically drop slowly (over several hours).

In 1988, researchers at Novo Research Institute in Denmark showed that insulin could be genetically engineered to prefer the monomeric (active) state. They used recombinant DNA technology to produce insulin with an aspartate residue replacing a proline at the contact interface between adjacent subunits. The negative charge on the Asp side chain creates electrostatic repulsion between subunits and increases the dissociation constant for the hexamer $\rightleftharpoons$ monomer equilibrium. Injection of this mutant insulin into test animals produced more rapid decreases in blood glucose than did ordinary insulin. This mutant insulin, known as *insulin aspart*, marketed by the Danish pharmaceutical company Novo as NovoLog in the United States and as NovoRapid in Europe, has several advantages over ordinary insulin in the treatment of diabetes. NovoLog (<http://www.novolog.com>) has a faster rate of absorption, a faster onset of action, and a shorter duration of action than regular human insulin. It is particularly suited for mealtime dosing to control postprandial glycemia, the rise in blood sugar following consumption of food. Regular human insulin acts more slowly, so patients must usually administer it 30 minutes before eating.

the radius squared and volume is a function of the radius cubed.) Because interactions within the protein usually tend to stabilize the protein and because the interaction of the protein surface with solvent water is often energetically unfavorable, decreased surface-to-volume ratios usually result in more stable proteins. Subunit association may also serve to shield hydrophobic residues from solvent water. Subunits that recognize either themselves or other subunits avoid any errors arising in genetic translation by binding mutant forms of the subunits less tightly.

Genetic Economy and Efficiency Oligomeric association of protein monomers is genetically economical for an organism. Less DNA is required to code for a monomer that assembles into a homomultimer than for a large polypeptide of the same molecular mass. Another way to look at this is to realize that virtually all of the information that determines oligomer assembly and subunit–subunit interaction is contained in the genetic material needed to code for the monomer. For example, HIV protease, an enzyme that is a dimer of identical subunits, performs a catalytic function similar to homologous cellular enzymes that are single polypeptide chains of twice the molecular mass.

Bringing Catalytic Sites Together Many enzymes derive at least some of their catalytic power from oligomeric associations of monomer subunits. This can happen in several ways. The monomer may not constitute a complete enzyme active site. Formation of the oligomer may bring all the necessary catalytic groups together to form an active enzyme. For example, the active sites of bacterial glutamine synthetase are formed from pairs of adjacent subunits. The dissociated monomers are inactive.

Oligomeric enzymes may also carry out different but related reactions on different subunits. Thus, tryptophan synthase is a tetramer consisting of pairs of different subunits, $\alpha_2\beta_2$. Purified α -subunits catalyze the following reaction:

and the β -subunits catalyze this reaction:

Indole, the product of the α -reaction and the reactant for the β -reaction, is passed directly from the α -subunit to the β -subunit and cannot be detected as a free intermediate.

Cooperativity There is another, more important consequence when monomer subunits associate into oligomeric complexes. Most oligomeric enzymes regulate catalytic activity by means of subunit interactions, which may give rise to cooperative phenomena. Multi-subunit proteins typically possess multiple binding sites for a given ligand. If the binding of ligand at one site changes the affinity of the protein for ligand at the other binding sites, the binding is said to be **cooperative**. Information transfer in this manner across long distances in proteins is termed **allostery**, literally action “at another site.” Increases in affinity at subsequent sites represent positive cooperativity, whereas decreases in affinity correspond to negative cooperativity. The points of contact between protein subunits provide a mechanism for this signal transduction through the protein structure and for communication between the subunits. This in turn provides a way in which the binding of ligand to one subunit can influence the binding behavior at the other subunits. Such cooperative behavior is the underlying mechanism for regulation of many biological processes.

Foundational Biochemistry
 Things You Should Know after Reading Chapter 6.

- The secondary, tertiary, and quaternary structures of proteins are stabilized by weak forces.
- Secondary structures arise through hydrogen bond formation.
- Protein folding is driven predominantly by hydrophobic interactions.
- Charged residues are found mainly on the surface of proteins; hydrophobic residues are located mainly in the protein interior.
- All the information necessary for folding a polypeptide into its physiological structure is contained in the amino acid sequence of the peptide.
- The conformation of the peptide backbone is known if the ϕ and ψ angles of each amide plane are known.
- The nature and dimensions of the α -helix and β -sheet and β -turn and how each is stabilized by hydrogen bonds.
- The nature and structure of α - and β -keratin and the collagen helix.
- The reason why helices and sheets comprise the core of most globular proteins.
- Waters on the protein surface stabilize globular structures.
- Packing densities of globular proteins are typically 0.75; most of the space is small cavities that provide flexibility and facilitate protein dynamics.
- Protein domains are nature's modular strategy for protein design.
- Many proteins, especially proteins larger than 250 residues, consist of two or more domains.
- Denaturation leads to loss of structure and function; proteins can be renatured under certain conditions.
- Levinthal's paradox supports the hypothesis that proteins fold by concerted mechanisms.
- Folding of globular proteins typically involves a hydrophobic collapse and transient protein states, such as molten globules.
- The largest contribution to the stability of folded proteins is the entropy change for the waters associated with its nonpolar residues.
- Marginal stability contributes to flexibility and motion in proteins.
- The types of motion in proteins and the time scale of each.
- Polypeptide chains made from L-amino acids tend to undergo right-handed twists.
- Most globular proteins can be conceptualized as "layer structures."
- The four classes of globular protein structure: all α proteins, all β proteins, α/β proteins, and $\alpha + \beta$ proteins.
- Unstructured proteins can adapt to bind to multiple ligands, thus exerting multiple functions.
- The weak forces that modulate subunit interactions in multimeric proteins are similar to those that stabilize protein monomers.
- Open quaternary proteins structures can polymerize.
- The structural and functional advantages of subunit association include stability, genetic economy and efficiency, juxtaposition of catalytic sites, and cooperativity.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Determining the Length of a Keratin Molecule** The central rod domain of a keratin protein is approximately 312 residues in length. What is the length (in Å) of the keratin rod domain? If this same peptide segment were a true α -helix, how long would it be? If the same segment were a β -sheet, what would its length be?
- Calculating the Rate of Collagen Helix Growth** A teenager can grow 4 inches in a year during a growth spurt. Assuming that the increase in height is due to vertical growth of collagen fibers (in bone), calculate the number of collagen helix turns synthesized per minute.
- Assessing the Roles of Weak Forces Between Amino Acids in Proteins** Discuss the potential contributions to hydrophobic and van der Waals interactions and ionic and hydrogen bonds for the side chains of Asp, Leu, Tyr, and His in a protein.
- Secondary Structures** Give a possible explanation as to why so many proteins, independent of their primary structure, contain α -helices or β -sheets in their tertiary structure.
- Conformation of Collagen** Collagen protein forms triple helical, quaternary structures (see Figure 6.16) and is rich in modified proline and lysine amino acids called hydroxyproline or hydroxylysine. Explain why the presence of these modified proline or lysine amino acids is crucial to the conformation of collagen.
- Hydrophobicity/Hydrophilicity Balance of Amino Acids** Consider the amino acid composition of three different proteins. Which of these three proteins has the appropriate balance of hydrophobic, hydrophilic, and amphiphilic amino acids in the context of the folding

of proteins discussed in section 6.4? (Revisit Section 4.1d for the classification of amino acids.)

Protein A		Protein B		Protein C	
%	%	%	%	%	%
A 4.3	M 2.5	A 8.9	M 3.0	A 1.7	M 1.6
C 4.8	N 3.7	C 3.5	N 2.7	C 8.1	N 6.2
D 3.5	P 5.0	D 2.6	P 6.3	D 9.8	P 2.1
E 6.0	Q 6.3	E 2.6	Q 2.7	E 8.3	Q 8.9
F 5.0	R 4.8	F 8.7	R 2.9	F 2.9	R 6.8
G 4.2	S 8.2	G 5.1	S 5.0	G 3.4	S 10.2
H 4.1	T 4.7	H 2.9	T 2.0	H 9.0	T 9.3
I 4.5	V 4.5	I 8.0	V 10.9	I 2.1	V 2.1
K 9.0	W 5.6	K 2.9	W 6.2	K 1.4	W 1.7
L 3.9	Y 5.4	L 7.1	Y 6.0	L 2.4	Y 2.0

- Amino Acid Structure in Proteins** Amino acids typically consist of a central carbon atom. Attached to this central carbon are an amino group, a carboxylic acid group, a side chain (the R group), and a hydrogen. If the α -hydrogens of amino acids were replaced by a second side chain (second R group), amino acids could still form proteins. What may be the effect of amino acids with two side chains on protein structure?

8. **The Role of Proline Residues in β -Turns** Proline is the amino acid least commonly found in α -helices but most commonly found in β -turns. Discuss the reasons for this behavior.
9. **Assessing the Cross-Overs of Flavodoxin** For flavodoxin (PDB id = 5NLL), identify the right-handed cross-overs and the left-handed cross-overs in the parallel β -sheet.
10. **Assessing the Range of ϕ and ψ Angles in Proteins** Choose any three regions in the Ramachandran plot and discuss the likelihood of observing that combination of ϕ and ψ in a peptide or protein. Defend your answer using suitable molecular models of a peptide.
11. **Protein Structure Evaluation Based on Gel Filtration Data** A new protein of unknown structure has been purified. Gel filtration chromatography reveals that the physiological protein has a molecular weight of 240,000. Chromatography in the presence of 6 M guanidine hydrochloride yields a single peak corresponding to a protein of M_r 60,000. Chromatography in the presence of 6 M guanidine hydrochloride and 10 mM β -mercaptoethanol yields peaks for proteins of M_r 34,000 and 26,000. Explain what can be determined about the structure of this protein from these data.
12. **Understanding the Role of Amino Acids in Oligomerization Behavior** Two polypeptides, A and B, have similar tertiary structures, but A normally exists as a monomer, whereas B exists as a tetramer, B_4 . What differences might be expected in the amino acid composition of A versus B?
13. **Evaluation of α -Helices in Proteins** The hemagglutinin protein in influenza virus contains a remarkably long α -helix, with 53 residues.
- How long is this α -helix (in nm)?
 - How many turns does this helix have?
 - The typical residue in an α -helix is involved in two H bonds. How many H bonds are present in this helix?
14. **Understanding the Role of Gly Residues in Protein Secondary and Tertiary Structure** It is often observed that Gly residues are conserved in proteins to a greater degree than other amino acids. From what you have learned in this chapter, suggest a reason for this observation.
15. **Understanding H-Bond Formation in Proteins** Which amino acids would be capable of forming H bonds with a lysine residue in a protein?
16. **Assessing the pH Dependence of Poly-L-Glutamate Structure** Poly-L-glutamate adopts an α -helical structure at low pH but becomes a random coil above pH 5. Explain this behavior.
17. **Exploring the Dimensions of the α -Helix and Coiled Coils** Imagine that the dimensions of the α helix were such that there were exactly 3.5 amino acids per turn instead of 3.6. What would be the consequences for coiled-coil structures?
18. **(Research Problem) The Nature and Roles of Linear Motifs in Proteins** In addition to domains and modules, there are other significant sequence patterns in proteins—known as *linear motifs*—that are associated with a particular function. Consult the biochemical literature to answer the following questions:
- What are linear motifs?
 - How are they different from domains?
 - What are their functions?
 - How can they be characterized?
- There are several papers that are good starting points for this problem: Neduva, V., and Russell, R., 2005. Linear motifs: evolutionary interaction switches. *FEBS Letters* **579**:3342–3345.
- Gibson, T., 2009. Cell regulation: determined to signal discrete cooperation. *Trends in Biochemical Sciences* **34**:471–482.
- Diella, F., Haslam, N., Chica, C. et al., 2009. Understanding eukaryotic linear motifs and their role in cell signaling and regulation. *Frontiers of Bioscience* **13**:6580–6603.
19. **(Research Problem) The Nature of Protein–Protein Interactions** How do proteins interact? When one protein binds to another, one or both changes conformation. Two hypotheses have been proposed to describe such binding: In the induced fit model, the interaction between a protein and a ligand induces a conformation change (in the protein or ligand) through a stepwise process. In the conformational selection model, the unliganded protein (in the absence of the ligand) exists as an ensemble of conformations in a dynamic equilibrium. The binding ligand interacts preferentially with one among many of these conformations and shifts the equilibrium in favor of the selected conformation. Three recent papers shed light on this question:
- Boehr, D., and Wright, P. E., 2008. How do proteins interact? *Science* **320**:1429–1430.
- Gsponer, J., et al., 2008. A coupled equilibrium shift mechanism in calmodulin-mediated signal transduction. *Structure* **16**:736–746.
- Lange, O., et al., 2008. Recognition dynamics up to microseconds revealed from an RDC-derived ubiquitin ensemble in solution. *Science* **320**:1471–1475.
- Consult these papers and answer the following questions:
- What proteins were studied in these papers?
 - What techniques were used, and what time scales of protein motion were studied?
 - What were the conclusions of these papers, and how do these results illuminate the choice between induced fit and conformational selection in protein-protein interactions?
20. **(Research Problem) Conformational Transitions in Proteins** How do proteins accomplish conformational changes? How is it that proteins convert precisely and efficiently from one conformation to another? Recall from Figure 6.34 that any folding/unfolding transition must involve movement across a free-energy landscape, and try to imagine the nature of a conformational transition. Are bonds formed and broken along the way? What kinds of bonds and interactions might be involved? Suggest how such conformational transitions might occur. One reference that will be useful in this regard is:
- Boehr, D., 2009. During transitions proteins make fleeting bonds. *Cell* **139**:1049–1051.
21. **(Historical Context) The Third Person of the α -Helix Publication** Who was Herman Branson? What was his role in the elucidation of the structure of the α -helix? Did he receive sufficient credit and recognition for his contributions? And how did the rest of his career unfold? Do a Google search on Herman Branson to learn about his life, and read the article by David Eisenberg under Further Reading. You may also wish to examine the original paper by Pauling, Corey, and Branson as well as the following web site:
- <http://www.pnas.org/site/misc/classics1.shtml>
- Pauling, L., Corey, R. B., and Branson, H. R., 1951. The structure of proteins: two hydrogen-bonded helical configurations of the polypeptide chain. *Proceedings of the National Academy of Sciences, USA* **37**:235–240.
22. **Predicting Secondary Structure on the Basis of Sequence** Consider the following peptide sequences:
- EANQIDEMLYNVQCSLTTLTLEDTPVW
 LGVHLDITVPLSWTWTLTVKL
 QQNWGGLVVILTLVWFLM
 CNMKHGDSDQCDERTYP
 YTREQSDGHIPKMNCDS
 AGPFGPDGPTIGPK
- Which of the preceding sequences would be likely to be found in each of the following:
- A parallel β -sheet
 - An antiparallel β -sheet
 - A tropocollagen molecule
 - The helical portions of a protein found in your hair

- 23. Drawing Secondary Structures** To fully appreciate the elements of secondary structure in proteins, it is useful to have a practical sense of their structures. On a piece of paper, draw a simple but large zigzag pattern to represent a β -strand. Then fill in the structure, drawing the locations of the atoms of the chain on this zigzag pattern. Then draw a simple, large coil on a piece of paper to represent an α -helix. Then fill in the structure, drawing the backbone atoms in the correct locations along the coil and indicating the locations of the R groups in your drawing.
- 24. Calculating ΔG for a Monomer-to-Dimer Transition** The dissociation constant for a particular protein dimer is $1 \mu\text{M}$. Calculate the free energy difference for the monomer-to-dimer transition.
- 25. Calculating ΔG for a State Change** Consider a protein that can exist in two forms: folded and unfolded. Calculate the free energy difference at 298 K between a state in which 80% of the protein is folded and a state in which 80% of the protein is unfolded.
- 26. Analyzing a Small Element of Tertiary Structure** Consider a protein structure consisting of a $\beta\alpha\beta$ loop, with β -bends linking the ends of the α -helix to the β -strands. If the length of the α -helix and the lengths of each β -strand are all the same (4.2 nm):
- How many amino acid residues does the α -helical segment contain?
 - How many turns does this α -helix have?
 - How many amino acid residues does each β -strand contain?
 - What is the total number of amino acid residues in the complete $\beta\alpha\beta$ structure?
 - Approximately how many hydrogen bonds do you think this $\beta\alpha\beta$ structure has?
- 27. Determining the Charge of a Peptide** Consider the peptide EYSTKKHTR. Assuming that the pK_a values for the ionizable groups in this peptide are the same as in the free amino acids, what is the charge on this peptide at pH 9.8? Explain your answer in detail.

28. Determining the Charge of a Peptide Consider the peptide WDSTRKHCR. Assuming that the pK_a values for the ionizable groups in this peptide are the same as in the free amino acids, what is the charge on this peptide at pH 6? Explain your answer in detail.

29. Assessing the Structural Consequences of Protein Mutations The B.1.1.7 strain of the novel SARS-CoV-2 coronavirus has several mutations in its spike protein, including:

N501Y A570D P681H D1118H

Consider each of these mutated positions in the spike protein and describe the possible consequences for the spike protein structure and for binding to potential ligands, such as human cell surface proteins.

Think-Pair-Share question

Secondary Structures as Modules The figure shows crude representations of amino acid segments that could be α -helices, parts of a β -sheet or have no specific structure.

Challenge a fellow student (and receive a similar challenge) to construct crude protein models following specific requirements with increasing complexity.

A couple of examples are suggested:

Example 1: Construct a protein model consisting of five segments built from one β -sheet with at least two segments, one α -helix and one amorphous segment.

Example 2: Construct a protein model containing 15 amino acid segments, at least two α -helices, at least three β -sheets containing a minimum of three amino acid segments, not more than three amorphous segments and no two α -helices or amorphous segments should be connected to each other.

◀ “The Discovery of Honey”—Piero di Cosimo (1492).
Honey is mostly carbohydrates.

Essential Question

Carbohydrates are a versatile class of molecules of the formula $(\text{CH}_2\text{O})_n$. They are a major form of stored energy in organisms, and they are the metabolic precursors of virtually all other biomolecules. Conjugates of carbohydrates with proteins and lipids perform a variety of functions, including recognition events that are important in cell growth, transformation, and other processes. **What are the structure, chemistry, and biological function of carbohydrates?**

Carbohydrates are the single most abundant class of organic molecules found in nature. Energy from the sun captured by green plants, algae, and some bacteria during photosynthesis converts more than 250 billion kilograms of carbon dioxide into carbohydrates every day on earth. In turn, carbohydrates are the metabolic precursors of virtually all other biomolecules. Breakdown of carbohydrates provides the energy that sustains animal life. Carbohydrates can be covalently linked with a variety of other molecules. These **glycoconjugates** are important components of cell walls and extracellular structures in plants, animals, and bacteria. In addition to the structural roles such molecules play, they serve in a variety of processes involving *recognition* between cell types or recognition of cellular structures by other molecules. Recognition events are important in normal cell growth, fertilization, transformation of cells, and other processes.

All of these functions are made possible by the characteristic chemical features of carbohydrates:

- The existence of at least one and often two or more asymmetric centers
- The ability to exist either in linear or ring structures
- The capacity to form polymeric structures via *glycosidic* bonds
- The potential to form multiple hydrogen bonds with water or other molecules in their environment

Key Questions

- 7.1 How Are Carbohydrates Named?
- 7.2 What Are the Structure and Chemistry of Monosaccharides?

- 7.5 What Are Glycoproteins, and How Do They Function in Cells?
- 7.6 How Do Proteoglycans Modulate Processes in Cells and Organisms?
- 7.7 How Do Carbohydrates Provide a Structural Code?

7.1 | How Are Carbohydrates Named?

The name *carbohydrate* arises from the basic molecular formula $(\text{CH}_2\text{O})_n$, where $n = 3$ or more. $(\text{CH}_2\text{O})_n$ can be rewritten $(\text{C}\cdot\text{H}_2\text{O})_n$ to show that these substances are hydrates of carbon.

Carbohydrates are generally classified into three groups: **monosaccharides** (and their derivatives), **oligosaccharides**, and **polysaccharides**. The monosaccharides are also called **simple sugars** and have the formula $(\text{CH}_2\text{O})_n$. Monosaccharides cannot be broken down into smaller sugars under mild conditions. Oligosaccharides derive their name from the Greek word *oligo*, meaning “few,” and consist of two to ten simple sugar residues. Disaccharides are common in nature, and trisaccharides also occur frequently. Four- to six-sugar-unit oligosaccharides are usually bound covalently to other molecules, including glycoproteins. As their name suggests, polysaccharides are polymers of the simple sugars and their derivatives. They may be either linear or branched polymers and may contain hundreds or even thousands of monosaccharide units. Their molecular weights range up to 1 million or more.

Careers in Chemistry

Dr. Shannon Timmons

Dr. Shannon Timmons was born in Nova Scotia, Canada where she was inspired to pursue a career in science based on her admiration of a woman in her community who was a leader in public health. After encouragement from her introductory chemistry professor, she earned her Bachelor of Science in Chemistry from Acadia University and her Ph.D. in Medical Chemistry from Dalhousie University. Her Ph.D. research involved the development of new chemical and enzymatic methods to synthesize sugar nucleotides, the building blocks of carbohydrate polymers.

In 2008, Dr. Timmons joined the faculty of Lawrence Technological University in Southfield, Michigan, where she teaches organic chemistry, biochemistry, and serves as chair of the Department of Natural Sciences. As a professor, she values inclusivity and takes care to highlight the contributions of women and people of color in chemistry and biology so that more students may feel emboldened to pursue careers in STEM fields. In her words, “The field of education is a calling that changes lives, and I feel privileged to have the opportunity to teach and mentor so many next-generation scientists.”

Figure 7.1 The D,L system of nomenclature is based on the structures of D- and L-glyceraldehyde.

(a) Structure of a simple aldose (glyceraldehyde) and a simple ketose (dihydroxyacetone). (b) The configurations of D- and L-glyceraldehyde.

7.2 | What Are the Structure and Chemistry of Monosaccharides?

Monosaccharides are ubiquitous in nature. This section describes their nomenclature, structures, and chemistry.

7.2a Monosaccharides Are Classified as Aldoses and Ketoses

Monosaccharides consist typically of three to seven carbon atoms and are described either as **aldoses** or **ketoses**, depending on whether the molecule contains an aldehyde function or a ketone group. The simplest aldose is glyceraldehyde, and the simplest ketose is dihydroxyacetone (Figure 7.1). These two simple sugars are termed **trioses** because they each contain three carbon atoms. The structures and names of a family of aldoses and ketoses with three, four, five, and six carbons are shown in Figures 7.2 and 7.3. *Hexoses* are the most abundant sugars in nature. Nevertheless, sugars from all these classes are important in metabolism.

Monosaccharides, either aldoses or ketoses, are often given more detailed generic names to describe both the important functional groups and the total number of carbon atoms. Thus, one can refer to *aldotetroses* and *ketotetroses*, *aldopentoses* and *keto-pentoses*, *aldohexoses* and *ketohexoses*, and so on. Sometimes the ketone-containing monosaccharides are named simply by inserting the letters *-ul-* into the simple generic

Figure 7.2 The structure and stereochemical relationships of D-aldoses with three to six carbons. The configuration in each case is determined by the highest numbered asymmetric carbon (shown in pink). In each row, the new asymmetric carbon is the lowest numbered and is shown in yellow. Blue highlights indicate the most common aldoses, D-glyceraldehyde, D-erythrose, D-ribose, D-glucose, D-mannose and D-galactose.

terms, such as *tetrols*, *pentuloses*, *hexuloses*, *heptuloses*, and so on. The simplest monosaccharides are water soluble, and most taste sweet.

7.2b Stereochemistry Is a Prominent Feature of Monosaccharides

Aldoses with at least three carbons and ketoses with at least four carbons contain **chiral centers** (see Chapter 4). The nomenclature for such molecules must specify the **configuration** about each asymmetric center, and drawings of these molecules must be based on a system that clearly specifies these configurations. As noted in Chapter 4, the **Fischer projection** system is used almost universally for this purpose today. The

Figure 7.3 The structure and stereochemical relationships of D-ketoses with three to six carbons. The configuration in each case is determined by the highest numbered asymmetric carbon (shown in pink). In each row, the new asymmetric carbon is the lowest numbered and is shown in yellow. Blue highlights indicate the most common ketoses, dihydroxyacetone, D-ribulose, and D-fructose.

structures shown in Figures 7.2 and 7.3 are Fischer projections. For monosaccharides with two or more asymmetric carbons, the prefix D or L refers to the configuration of the highest numbered asymmetric carbon (the asymmetric carbon farthest from the carbonyl carbon). A monosaccharide is designated D if the hydroxyl group on the highest numbered asymmetric carbon is drawn to the right in a Fischer projection, as in D-glyceraldehyde (Figure 7.1). Note that the designation D or L merely relates the configuration of a given molecule to that of glyceraldehyde and does *not* specify the sign of rotation of plane-polarized light. If the sign of optical rotation is to be specified in the name, the convention of D or L designations may be used along with a + (plus) or – (minus) sign. Thus, D-glucose (Figure 7.2) may also be called D(+)-glucose because it is dextrorotatory, whereas D-fructose (Figure 7.3), which is levorotatory, can also be named D(–)-fructose.

All of the structures shown in Figures 7.2 and 7.3 are D-configurations, and the D-forms of monosaccharides predominate in nature, just as L-amino acids do. These preferences, established by apparently random choices early in evolution, persist uniformly in nature because of the stereospecificity of the enzymes that synthesize and metabolize these small molecules. L-Monosaccharides do exist in nature, serving a few relatively specialized roles. L-Galactose is a constituent of certain polysaccharides, and L-arabinose is a constituent of bacterial cell walls.

According to convention, the D- and L-forms of a monosaccharide are *mirror images* of each other, as shown in Figure 7.4 for fructose. Stereoisomers that are nonsuperimposable mirror images of each other are called **enantiomers**, or sometimes *enantiomeric pairs*. For molecules that possess two or more chiral centers, more than two stereoisomers can exist. Pairs of isomers that have opposite configurations at one or more of the chiral centers but that are not mirror images of each other are called **diastereomers** or *diastereomeric pairs*. Any two structures in a given row in Figures 7.2 and 7.3 are diastereomeric pairs. Two sugars that differ in configuration at only one chiral center are described as **epimers**. For example, D-mannose and D-talose are epimers and D-glucose and D-mannose are epimers, whereas D-glucose and D-talose are *not* epimers but merely diastereomers.

7.2c Monosaccharides Exist in Cyclic and Anomeric Forms

Although Fischer projections are useful for presenting the structures of particular monosaccharides and their stereoisomers, they discount one of the most interesting facets of sugar structure—the ability to form cyclic structures with formation of an additional asymmetric center. Alcohols react readily with aldehydes to form **hemiacetals** (Figure 7.5). The British carbohydrate chemist Sir Norman Haworth showed that the linear form of glucose (and other aldohexoses) could undergo a similar *intramolecular* reaction to form a *cyclic hemiacetal*. The resulting six-membered, oxygen-containing ring is similar to *pyran* and is designated a **pyranose**. The reaction is catalyzed by acid (H^+) or base (OH^-) and is readily reversible.

In a similar manner, ketones can react with alcohols to form **hemiketals**. The analogous intramolecular reaction of a ketose sugar such as fructose yields a *cyclic hemiketal* (Figure 7.6). The five-membered ring thus formed is reminiscent of *furan* and is referred to as a **furanose**. The cyclic pyranose and furanose forms are the preferred structures for monosaccharides in aqueous solution. At equilibrium, the linear aldehyde or ketone structure is only a minor component of the mixture (generally much less than 1%).

Figure 7.4 D-Fructose and L-fructose, an enantiomeric pair. Note that changing the configuration only at C₅ would change D-fructose to L-sorbose.

 β -D-Glucopyranose

α -D-Glucopyranose

 β -D-Glucopyranose

FISCHER PROJECTION FORMULAS

Figure 7.5 Glucose can undergo an intramolecular reaction to form a cyclic hemiacetal. **(a)** Formation of a hemiacetal. **(b)** The linear form of D-glucose undergoes an intramolecular reaction to form a cyclic hemiacetal, shown as Haworth projections. **(c)** Cyclic pyranose forms, shown as Fischer projections.

Figure 7.6 Fructose can undergo an intramolecular reaction to form a cyclic hemiketal. (a) Formation of a hemiketal. (b) The linear form of D-fructose undergoes an intramolecular reaction to form a cyclic hemiketal, shown as Haworth projections. (c) Cyclic furanose forms shown as Fischer projections.

When hemiacetals and hemiketals are formed, the carbon atom that carried the carbonyl function becomes an asymmetric carbon atom. Isomers of monosaccharides that differ only in their configuration about that carbon atom are called **anomers**, designated as α or β , as shown in Figure 7.5, and the carbonyl carbon is thus called the **anomeric carbon**. When the hydroxyl group at the anomeric carbon is on the *same side* of a Fischer projection as the oxygen atom at the highest numbered asymmetric carbon, the configuration at the anomeric carbon is α , as in α -D-glucose. When the anomeric hydroxyl is on the *opposite side* of the Fischer projection, the configuration is β , as in β -D-glucopyranose (Figure 7.5).

Chiral molecules rotate plane-polarized light either clockwise or counter-clockwise, a property termed **optical rotation**. The addition of a new asymmetric center upon hemiacetal and hemiketal formation alters the optical rotation properties of monosaccharides, and the original assignment of the α and β notations arose from studies of these properties. Early carbohydrate chemists frequently observed that the optical rotation of glucose (and other sugar) solutions could change with time, a process called **mutarotation**. This indicated that a structural change was occurring. It was eventually found that α -D-glucose has a specific optical rotation, $[\alpha]_D^{20}$, of 112.2° , and that β -D-glucose has a specific optical rotation of 18.7° . Mutarotation involves interconversion of α - and β -forms of the monosaccharide with intermediate formation of the linear aldehyde or ketone, as shown in Figures 7.5 and 7.6.

7.2d Haworth Projections Are a Convenient Device for Drawing Sugars

Another of Haworth's lasting contributions to the field of carbohydrate chemistry was his proposal to represent pyranose and furanose structures as hexagonal and pentagonal rings lying perpendicular to the plane of the paper, with thickened lines indicating the side of the ring closest to the reader. Such **Haworth projections**, which are now widely used to represent saccharide structures (Figures 7.5 and 7.6), show substituent

groups extending either above or below the ring. (A **substituent** is an atom or group of atoms taking the place of another atom or group or occupying a specified position in a molecule.) Substituents drawn to the left in a Fischer projection are drawn above the ring in the corresponding Haworth projection. Substituents drawn to the right in a Fischer projection are below the ring in a Haworth projection. Exceptions to these rules occur in the formation of furanose forms of pentoses and the formation of furanose or pyranose forms of hexoses. In these cases, the structure must be redrawn with a rotation about the carbon whose hydroxyl group is involved in the formation of the cyclic form (Figure 7.7) in order to orient the appropriate hydroxyl group for ring formation. This involves no change in configuration of the saccharide molecule.

The rules previously mentioned for assignment of α - and β -configurations can be readily applied to Haworth projection formulas. For the D-sugars, the anomeric hydroxyl group is below the ring in the α -anomer and above the ring in the β -anomer. For L-sugars, the opposite relationship holds.

As Figure 7.7 implies, in most monosaccharides there are two or more hydroxyl groups that can react with an aldehyde or ketone at the other end of the molecule to form a hemiacetal or hemiketal. Consider the possibilities for glucose, as shown in Figure 7.7. If the C-4 hydroxyl group reacts with the aldehyde of glucose, a five-membered ring is formed, whereas if the C-5 hydroxyl reacts, a six-membered ring is formed. The C-6 hydroxyl does not react effectively because a seven-membered ring is too strained to form a stable hemiacetal. The same is true for the C-2 and C-3 hydroxyls, and thus five- and six-membered rings are by far the most likely to be formed from six-membered monosaccharides. D-Ribose, with five carbons, readily forms either five-membered rings (α - or β -D-ribofuranose) or six-membered rings (α - or β -D-ribopyranose) (Figure 7.7). In general, aldoses and ketoses with five or more carbons can form *either* furanose or pyranose rings, and the more stable form depends on structural factors. The nature of the substituent groups on the carbonyl and hydroxyl groups and the configuration about the asymmetric carbon will determine whether a given monosaccharide prefers the pyranose or furanose structure. In general, the pyranose form is favored over the furanose ring for aldohexose sugars, although, as we shall see, furanose structures tend to be more stable for ketohexoses.

Although Haworth projections are convenient for displaying monosaccharide structures, they do not accurately portray the conformations of pyranose and furanose rings. Given C—C—C tetrahedral bond angles of 109° and C—O—C angles of 111° , neither pyranose nor furanose rings can adopt true planar structures. Instead, they take on puckered conformations, and in the case of pyranose rings, the two favored structures are the **chair conformation** and the **boat conformation**, as shown in Figure 7.8. Note that the ring substituents in these structures can be **equatorial**, which means approximately coplanar with the ring, or **axial**, that is, parallel to an axis drawn through the ring as shown.

Figure 7.7 D-Glucose, D-ribose, and other simple sugars can cyclize in two ways, forming either furanose or pyranose structures.

Figure 7.8 Conformations of simple sugars may be described in chair and boat representations. **(a)** Chair and boat conformations of a pyranose sugar. **(b)** Two possible chair conformations of β -D-glucose.

Two general rules dictate the conformation to be adopted by a given saccharide unit. First, bulky substituent groups on such rings are more stable when they occupy equatorial positions rather than axial positions, and second, chair conformations are slightly more stable than boat conformations. For a typical pyranose, such as β -D-glucose, there are two possible chair conformations (Figure 7.8). Of all the D-aldohexoses, β -D-glucose is the only one that can adopt a conformation with all its bulky groups in an equatorial position. With this advantage of stability, it may come as no surprise that β -D-glucose is the most widely occurring organic group in nature and the central hexose in carbohydrate metabolism.

7.2e Monosaccharides Can Be Converted to Several Derivative Forms

A variety of chemical and enzymatic reactions produce *derivatives* of the simple sugars. These modifications produce a diverse array of saccharide derivatives. Some of the most common derivations are discussed here.

Sugar Acids Sugars with free anomeric carbon atoms are reasonably good reducing agents and will reduce hydrogen peroxide, ferricyanide, certain metals (Cu^{2+} and Ag^+), and other oxidizing agents. Such reactions convert the sugar to a **sugar acid**. For example, addition of alkaline CuSO_4 (called *Fehling's solution*) to an aldose sugar produces a red cuprous oxide (Cu_2O) precipitate:

and converts the aldose to an *aldonic acid*, such as *gluconic acid* (Figure 7.9). Formation of a precipitate of red Cu_2O constitutes a positive test for an aldehyde. Carbohydrates that can reduce oxidizing agents in this way are referred to as **reducing sugars**. By quantifying the amount of oxidizing agent reduced by a sugar solution, one can accurately determine the concentration of the sugar. *Diabetes mellitus* is characterized by high levels of glucose in urine and blood and frequent analysis of reducing sugars in diabetic patients is an important part of the diagnosis and treatment of this disease. Over-the-counter kits for the easy and rapid determination of reducing sugars have made this procedure a simple one for diabetic persons.

Monosaccharides can be oxidized enzymatically at C-6, yielding *uronic acids*, such as **D-glucuronic** and **L-iduronic acids** (Figure 7.9). L-Iduronic acid is similar to D-glucuronic acid, except it has an opposite configuration at C-5. Oxidation at both C-1 and C-6 produces **aldaric acids**, such as **D-glucaric acid**.

Figure 7.9 Oxidation of D-glucose to sugar acids. Oxidized positions are highlighted. D-Gluconic acid and other aldonic acids exist in equilibrium with lactone structures.

Figure 7.10 Structures of some sugar alcohols. (Note that *myo*-inositol is a polyhydroxy cyclohexane, not a sugar alcohol.)

Sugar Alcohols Sugar alcohols, another class of sugar derivative, can be prepared by the mild reduction (with NaBH_4 or similar agents) of the carbonyl groups of aldoses and ketoses. Sugar alcohols, or **alditols**, are designated by the addition of *-itol* to the name of the parent sugar (Figure 7.10). The alditols are linear molecules that cannot cyclize in the manner of aldoses. Nonetheless, alditols are characteristically sweet tasting, and **sorbitol**, **mannitol**, and **xylitol** are widely used to sweeten sugarless gum

Figure 7.11 Sugar alcohols such as sorbitol, mannitol, and xylitol sweeten many sugarless gums and candies.

and mints (Figure 7.11). Sorbitol buildup in the eyes of diabetic persons is implicated in cataract formation. **Glycerol** and **myo-inositol**, a cyclic alcohol, are components of lipids (see Chapter 8). There are nine different stereoisomers of inositol; the one shown in Figure 7.10 was first isolated from heart muscle and thus has the prefix *myo*- for muscle. **Ribitol** is a constituent of flavin coenzymes (see Chapter 19).

Deoxy Sugars The **deoxy sugars** are monosaccharides with one or more hydroxyl groups replaced by hydrogens. 2-Deoxy-D-ribose (Figure 7.12), whose systematic name is 2-deoxy-D-erythropentose, is a constituent of DNA in all living things.

Honey—An Ancestral Carbohydrate Treat

Honey, the first sweet known to humankind, is the only sweetening agent that can be stored and used exactly as produced in nature. Bees process the nectar of flowers so that their final product is able to survive long-term storage at ambient temperature. Honey has been used as ceremonial material, medicinal agent, and food sweetener since at least 2500 BCE, when Ancient Egyptians developed beekeeping. Only in modern times have cane and beet sugar surpassed honey as the most frequently used sweetener. What is the chemical nature of this magical, viscous substance?

The bees' processing of honey consists of (1) reducing the water content of the nectar (30% to 60%) to the self-preserving range of 15% to 19%, (2) hydrolyzing the significant amount of sucrose in nectar to glucose and fructose by the action of the enzyme invertase, and (3) producing small amounts of gluconic acid from glucose by the action of the enzyme *glucose oxidase*. Most of the sugar in the final product is glucose and fructose, and the final product is supersaturated with respect to these monosaccharides. Honey actually consists of an emulsion of microscopic glucose hydrate and fructose hydrate crystals in a thick syrup. Sucrose accounts for only about 1% of the sugar in the final product, with fructose at about 38% and glucose at 31% by weight.

Figure 1 shows a ^{13}C nuclear magnetic resonance spectrum of honey from a mixture of wildflowers in southeastern Pennsylvania. Interestingly, five major hexose species contribute to this spectrum. Although it is often assumed that fructose exists exclusively in its furanose form, the predominant form of fructose in honey (67% of total fructose) is β -D-fructopyranose, with the β - and α -fructofuranose forms accounting for 27% and 6% of the fructose, respectively

(Figure 2). In polysaccharides, fructose invariably prefers the furanose form, but free fructose (and crystalline fructose) is predominantly β -fructopyranose, which is sweeter than the furanose form.

Figure 2 The principal forms of fructose found in honey.

Figure 7.12 Several deoxy sugars. Hydrogen and carbon atoms highlighted in red circles are “deoxy” positions.

Figure 7.13 Three sugar esters that play an important role in metabolism (phosphate groups highlighted in orange.)

Deoxy sugars also occur frequently in glycoproteins and polysaccharides. L-Fucose and L-rhamnose, both 6-deoxy sugars, are components of some cell walls, and rhamnose is a component of **ouabain**, a highly toxic *cardiac glycoside* found in the bark and root of the ouabaio tree. Ouabain is used by the east African Somalis as an arrow poison. The sugar moiety is not the toxic part of the molecule (see Chapter 9).

Sugar Esters The phosphate esters of glucose, fructose, and other monosaccharides are important metabolic intermediates, and the ribose moiety of nucleotides such as ATP and GTP is phosphorylated at the 5'-position (Figure 7.13).

Amino Sugars The amino sugars, including **D-glucosamine** and **D-galactosamine** (Figure 7.14), contain an amino group instead of a hydroxyl group at the C-2 position. They are found in many oligosaccharides and polysaccharides, including *chitin*, a polysaccharide in the exoskeletons of crustaceans and insects.

Muramic acid and neuraminic acid **Muramic acid** and **neuraminic acid**, which are components of the polysaccharides of cell membranes of higher organisms and also bacterial cell walls, are glycosamines linked to three-carbon acids at the C-1 or C-3 positions. In muramic acid (thus named as an *amine* isolated from bacterial cell wall polysaccharides; *murus* is Latin for “wall”), the hydroxyl group of a lactic acid moiety makes an ether linkage to the C-3 of glucosamine. Neuraminic acid (an *amine* isolated from *neural* tissue) forms a C—C bond between the C-1 of *N*-acetylmannosamine and the C-3 of pyruvic acid (Figure 7.15). The *N*-acetyl and *N*-glycolyl derivatives of neuraminic acid are collectively known as **sialic acids** and are distributed widely in bacteria and animal systems.

Acetals, Ketals, and Glycosides Hemiacetals and hemiketals can react with alcohols in the presence of acid to form **acetals** and **ketals**, as shown in Figure 7.16. This reaction is another example of a *dehydration synthesis* and is similar in this respect to the reactions undergone by amino acids to form peptides and nucleotides to form nucleic acids. The pyranose and furanose forms of monosaccharides react with alcohols in this way to form **glycosides** with retention of the α - or β -configuration at the C-1 carbon. The new bond between the anomeric carbon atom and the oxygen atom of the alcohol is called a **glycosidic bond**. Glycosides are named according to the parent monosaccharide. For example, *methyl- β -D-glucoside* (Figure 7.17) can be considered a derivative of β -D-glucose.

Figure 7.14 Structures of D-glucosamine and D-galactosamine.

Figure 7.17 The anomeric forms of methyl-D-glucoside.

Figure 7.16 Acetals and ketals can be formed from hemiacetals and hemiketals, respectively.

7.3 What Are the Structure and Chemistry of Oligosaccharides?

Given the relative complexity of oligosaccharides and polysaccharides in higher organisms, it is perhaps surprising that these molecules are formed from relatively few different monosaccharide units. (In this respect, the oligosaccharides and polysaccharides are similar to proteins; both form complicated structures based on a small number of different building blocks.) Monosaccharide units include the hexoses glucose, fructose, mannose, and galactose and the pentoses ribose and xylose.

7.3a Disaccharides Are the Simplest Oligosaccharides

The simplest oligosaccharides are the **disaccharides**, which consist of two monosaccharide units linked by a glycosidic bond. As in proteins and nucleic acids, each individual unit in an oligosaccharide is termed a *residue*. The disaccharides shown in Figure 7.18 are all commonly found in nature, with **sucrose**, **maltose**, and **lactose** being the most common. Each is a mixed acetal, with one hydroxyl group provided intramolecularly and one hydroxyl from the other monosaccharide. Except for sucrose, each of these structures possesses one free unsubstituted anomeric carbon atom, and thus each of these disaccharides is a reducing sugar. The end of the molecule containing the free anomeric carbon is called the **reducing end**, and the other end is called the **nonreducing end**. In the case of sucrose, both of the anomeric carbon atoms are substituted; that is,

Figure 7.18 The structures of several important disaccharides. Note that the notation “HOH” means that the configuration can be either α or β . If the —OH group is above the ring, the configuration is termed β . The configuration is α if the —OH group is below the ring. Also note that sucrose has no free anomeric carbon atom.

A Deeper Look

Trehalose—A Natural Protectant for Bugs

Insects use an open circulatory system to circulate *hemolymph* (insect blood). The “blood sugar” is not glucose but rather **trehalose**, an unusual, nonreducing disaccharide (see figure). Trehalose is found typically in organisms that are naturally subject to temperature variations and other environmental stresses—bacterial spores, fungi, yeast, and many insects. (Interestingly, honeybees do not have trehalose in their hemolymph, perhaps because they practice a colonial, rather than solitary, lifestyle. Bee colonies maintain a rather constant temperature of 18 °C, protecting the residents from large temperature changes.)

What might explain this correlation between trehalose utilization and environmentally stressful lifestyles? Konrad Bloch

suggests that trehalose may act as a natural cryoprotectant. Freezing and thawing of biological tissues frequently causes irreversible structural changes, destroying biological activity. High concentrations of polyhydroxy compounds, such as sucrose and glycerol, can protect biological materials from such damage. Trehalose is particularly well suited for this purpose and has been shown to be superior to other polyhydroxy compounds, especially at low concentrations. Support for this novel idea comes from studies by Paul Attfield, which show that trehalose levels in the yeast *Saccharomyces cerevisiae* increase significantly during exposure to high salt and high growth temperatures.

neither has a free —OH group. The substituted anomeric carbons cannot be converted to the aldehyde configuration and thus cannot participate in the oxidation–reduction reactions characteristic of reducing sugars. Thus, sucrose is *not* a reducing sugar.

Maltose, isomaltose, and cellobiose are all **homodisaccharides** because they each contain only one kind of monosaccharide, namely, glucose. Maltose is produced from starch (a polymer of α -D-glucose produced by plants) by the action of amylase enzymes and is a component of malt, a substance obtained by allowing grain (particularly barley) to soften in water and germinate. The enzyme **diastase**, produced during the germination process, catalyzes the hydrolysis of starch to maltose. Maltose is used in beverages (malted milk, for example). Because it is fermented readily by yeast, it is important in the brewing of beer. In both maltose and cellobiose, the glucose units are **1 $\rightarrow$ 4 linked**, meaning that the C-1 of one glucose is linked by a glycosidic bond to the C-4 oxygen of the other glucose. The only difference between them is in the configuration at the glycosidic bond. Maltose exists in the α -configuration, whereas cellobiose is a β -configuration. **Isomaltose** is obtained in the hydrolysis of some polysaccharides (such as dextran), and **cellobiose** is obtained from the acid hydrolysis of cellulose. Isomaltose also consists of two glucose units in a glycosidic bond, but in this case, C-1 of one glucose is linked to C-6 of the other, and the configuration is α .

The complete structures of these disaccharides can be specified in shorthand notation by using abbreviations for each monosaccharide, α or β , to denote configuration, and appropriate numbers to indicate the nature of the linkage. Thus, cellobiose is Glc β 1–4Glc, whereas isomaltose is Glc α 1–6Glc. Often the glycosidic linkage is written with an arrow so that cellobiose and isomaltose would be Glc β 1 $\rightarrow$ 4Glc and Glc α 1 $\rightarrow$ 6Glc, respectively. Because the linkage carbon on the first sugar is always C-1, a newer trend is to drop the 1– or 1 $\rightarrow$ and describe these simply as Glc β 4Glc and Glc α 6Glc, respectively. More complete names can also be used, however; for example, maltose would be O- α -D-glucopyranosyl-(1 $\rightarrow$ 4)-D-glucopyranose. Cellobiose, because of its β -glycosidic linkage, is formally O- β -D-glucopyranosyl-(1 $\rightarrow$ 4)-D-glucopyranose.

β -D-Lactose (O- β -D-galactopyranosyl-(1 $\rightarrow$ 4)-D-glucopyranose) (Figure 7.18) is the principal carbohydrate in milk and is of critical nutritional importance to mammals in the early stages of their lives. It is formed from D-galactose and D-glucose via a β (1 $\rightarrow$ 4) link, and because it has a free anomeric carbon, it is capable of mutarotation and is a reducing sugar. It is an interesting quirk of nature that lactose cannot be absorbed directly into the bloodstream. It must first be broken down into galactose and glucose by **lactase**, an intestinal enzyme that exists in young, nursing mammals but is not produced in significant quantities in the mature mammal. Most adult humans, with the exception of certain groups in Africa and northern Europe, produce only low levels of lactase. For most individuals, this is not a problem, but some cannot tolerate lactose and experience intestinal pain and diarrhea upon consumption of milk.

Sucrose, in contrast, is a disaccharide of almost universal appeal and tolerance. Produced by many higher plants and commonly known as *table sugar*, it is one of the products of photosynthesis and is composed of fructose and glucose. Sucrose has a specific optical rotation, $[\alpha]_D^{20}$, of $+66.5^\circ$, but an equimolar mixture of its component monosaccharides has a net negative rotation ($[\alpha]_D^{20}$ of glucose is $+52.5^\circ$ and of fructose is -92°). Sucrose is hydrolyzed by the enzyme **invertase**, so named for the inversion of optical rotation accompanying this reaction. Sucrose is also easily hydrolyzed by dilute acid. Although sucrose and maltose are important to the human diet, they are not taken up directly in the body. In a manner similar to lactose, they are first hydrolyzed by **sucrase** and **maltase**, respectively, in the human intestine.

7.3b A Variety of Higher Oligosaccharides Occur in Nature

In addition to the simple disaccharides, many other oligosaccharides are found in both prokaryotic and eukaryotic organisms, either as naturally occurring substances or as hydrolysis products of natural materials.

Human Biochemistry

Alpha-Gal and Red Meat Allergy

Many people in the southern United States and other parts of the world have become allergic to red meat in recent years. The cause turns out to be bites from certain ticks, including the lone star tick (*Amblyomma americanum*—see Figure 1). These tick bites trigger an immune response against the disaccharide galactose- α -1,3-galactose, known colloquially as “alpha-gal.” This moiety is synthesized in mammals by the enzyme α -1,3-galactosyltransferase and displayed on the extracellular surface of cells. The gene for this enzyme is inactivated in humans and other Old World primates, and for this reason alpha-gal decorations are not found on human cells. Ticks that have fed on other mammals can introduce alpha-gal into the human bloodstream via tick bites. Because alpha-gal is foreign to human cells, it is antigenic (that is, it provokes an immune response) and the human immune system produces anti-alpha-gal immunoglobulin E (IgE) antibodies. Once bitten, persons who eat red meat (such as beef, pork, and lamb) may experience a severe reaction, including swelling, hives, and anaphylaxis, within a few hours.

The link between tick bites and meat allergy was first identified in 2007 by Professor Sheryl van Nunen in Sydney, Australia. In 2008, Professor Thomas Platts-Mills and his colleagues at the University of Virginia found that patients administered cetuximab, a monoclonal antibody from mouse cells to treat certain cancers, later experienced a similar red meat allergy. They showed that the allergic responses to cetuximab and to tick bites were both due to alpha-gal. Ironically, while he was involved in the early stages of this work, Platts-Mills himself was bitten by lone star ticks while hiking one day, and he developed a red meat allergy.

It is interesting to note the similarity between alpha-gal and the human blood group A and B antigens, all three of which contain the galactose- α -1,3-galactose linkage. The blood group antigens both contain an L-fucose in β (1,2) linkage to the central galactose. Humans have galactosyltransferase enzymes that can add a second

galactose to the fucosyl- α 1,2-galactose precursor of the blood group antigens, but (as noted earlier), they lack the enzyme activity that would add a second galactose in α (1,3) linkage to a bare galactose to form alpha-gal (Figure 2).

Figure 2 Alpha-gal is galactose- α -1,3-galactose.

Figure 1 A lone-star tick.

Figure 7.19 Some antibiotics are oligosaccharides or contain oligosaccharide groups.

Oligosaccharides also occur widely as components (via glycosidic bonds) of *antibiotics* derived from various sources. Figure 7.19 shows the structures of two representative carbohydrate-containing antibiotics.

7.4 What Are the Structure and Chemistry of Polysaccharides?

Polysaccharides are polymers of the simple sugars and their derivatives. They may be either linear or branched polymers and may contain hundreds or even thousands of monosaccharide units. Polysaccharides mediate and provide a vast variety of functions in nature, including energy storage, recognition and signaling between cells, and support for cells and tissues.

7.4a Nomenclature for Polysaccharides Is Based on Their Composition and Structure

By far the majority of carbohydrate material in nature occurs in the form of polysaccharides. Polysaccharides include not only those substances composed only of glycosidically linked sugar residues, but also molecules that contain polymeric saccharide structures linked via covalent bonds to amino acids, peptides, proteins, lipids, and other structures.

Polysaccharides, also called **glycans**, are assembled from monosaccharides and their derivatives. If a polysaccharide contains only one kind of monosaccharide molecule, it is a **homopolysaccharide**, or **homoglycan**, whereas those containing more than one kind of monosaccharide are **heteropolysaccharides**. The most common constituent of polysaccharides is D-glucose, but D-fructose, D-galactose, L-galactose, D-mannose, L-arabinose, and D-xylose are also common. Common monosaccharide derivatives in polysaccharides include the amino sugars (D-glucosamine and D-galactosamine), their derivatives (*N*-acetylneuraminic acid and *N*-acetylmuramic acid), and simple sugar acids (glucuronic and iduronic acids). Polysaccharides differ not only in the nature of their component monosaccharides, but also in the length of their chains and in the amount of chain branching that occurs. Although a given sugar residue has only one anomeric carbon and thus can form only one glycosidic linkage with hydroxyl groups on other molecules, each sugar residue carries several hydroxyls, one or more of which may be an acceptor of glycosyl substituents (Figure 7.20). This ability to form branched structures distinguishes polysaccharides from proteins and nucleic acids, which occur only as linear polymers.

Figure 7.20 Amylose and amylopectin are the two forms of starch. Note that the linear linkages are $\alpha(1 \rightarrow 4)$ but the branches in amylopectin are $\alpha(1 \rightarrow 6)$. Branches in polysaccharides can involve any of the hydroxyl groups on the monosaccharide components. Amylopectin is a highly branched structure, with branches occurring every 12 to 30 residues.

7.4b Polysaccharides Serve Energy Storage, Structure, and Protection Functions

Polysaccharides function as storage materials, structural components, or protective substances. Thus, *starch* and *glycogen*, as readily metabolizable sources of glucose, provide energy reserves for cells. *Chitin* and *cellulose* provide strong support for the skeletons of arthropods and green plants, respectively. Mucopolysaccharides, such as the *hyaluronic acids*, form protective coats on animal cells. In each of these cases, the relevant polysaccharide is either a homopolymer or a polymer of small repeating units. Recent research indicates, however, that oligosaccharides and polysaccharides with varied structures may also be involved in much more sophisticated tasks in cells, including a variety of cellular recognition and intercellular communication events, as discussed later.

7.4c Polysaccharides Provide Stores of Energy

Organisms store carbohydrates in the form of polysaccharides rather than as monosaccharides to lower the osmotic pressure of the sugar reserves. Because osmotic pressures depend only on *numbers of molecules*, the osmotic pressure is greatly reduced by formation of a few polysaccharide molecules out of thousands (or even millions) of monosaccharide units.

Starch By far the most common storage polysaccharide in plants is **starch**, which exists in two forms: **α -amylose** and **amylopectin** (Figure 7.20). Most forms of starch in nature are 10% to 30% α -amylose and 70% to 90% amylopectin. α -Amylose is composed of linear chains of D-glucose in $\alpha(1 \rightarrow 4)$ linkages. The chains are of varying length, having molecular weights from several thousand to half a million. As can be seen from the structure in Figure 7.20, the chain has a reducing end and a nonreducing end. Although poorly soluble in water, α -amylose forms micelles in which the polysaccharide chain adopts a helical conformation (Figure 7.21). Iodine reacts with α -amylose to give a characteristic blue color (the well-known iodine test for starch), which arises from the insertion of iodine into the hydrophobic middle of the amylose helix.

Amylopectin is a highly branched chain of glucose units (one branch is shown in Figure 7.20). Branches occur in these chains every 12 to 30 residues. The average branch length is between 24 and 30 residues, and molecular weights of amylopectin molecules can range up to 100 million. The linear linkages in amylopectin are $\alpha(1 \rightarrow 4)$, whereas

Figure 7.21 Suspensions of amylose in water adopt a helical conformation. Iodine (I_2) can insert into the middle of the amylose helix to give a blue color that is characteristic and diagnostic for starch.

Figure 7.22 The starch phosphorylase reaction cleaves glucose residues from amylose, producing α -D-glucose-1-phosphate.

the branch linkages are $\alpha(1 \rightarrow 6)$. As is the case for α -amylose, amylopectin forms micellar suspensions in water; iodine reacts with such suspensions to produce a red-violet color.

Starch is stored in plant cells in the form of granules in the stroma of plastids (plant cell organelles). When starch is to be mobilized and used by the plant that stored it, it is split into its monosaccharide elements by stepwise phosphorolytic cleavage of glucose units, a reaction catalyzed by **starch phosphorylase** (Figure 7.22). The products are one molecule of glucose-1-phosphate and a starch molecule with one less glucose unit. In α -amylose, this process continues all along the chain until the end is reached.

In animals, digestion and use of plant starches begin in the mouth with **salivary α -amylase** ($\alpha(1 \rightarrow 4)$ -glucan 4-glucanohydrolase), the major enzyme secreted by the salivary glands. Although the capability of making and secreting salivary α -amylases is widespread in the animal world, some animals (such as cats, dogs, birds, and horses) do not secrete them. Salivary α -amylase is an **endoamylase** that splits $\alpha(1 \rightarrow 4)$ glycosidic linkages only within the chain. Raw starch is not very susceptible to salivary endoamylase. However, when suspensions of starch granules are heated, the granules swell, taking up water and causing the polymers to become more accessible to enzymes. This is why cooked starch is more digestible. Most starch digestion occurs in the small intestine via glycolylases.

Glycogen The major form of storage polysaccharide in animals is **glycogen**. Glycogen is found mainly in the liver (where it may amount to as much as 10% of liver mass) and skeletal muscle (where it accounts for 1% to 2% of muscle mass). Liver glycogen consists of granules containing highly branched molecules, with $\alpha(1 \rightarrow 6)$ branches occurring every 8 to 12 glucose units. Like amylopectin, glycogen yields a red-violet color with iodine. Glycogen can be hydrolyzed by both α - and β -amylases, yielding glucose and maltose, respectively, as products and can also be hydrolyzed by **glycogen phosphorylase**, an enzyme present in liver and muscle tissue, to release glucose-1-phosphate for glycolysis.

Dextran Another important family of storage polysaccharides is the **dextrans**, which are $\alpha(1 \rightarrow 6)$ -linked polysaccharides of D-glucose with branched chains found in yeast and bacteria. Because the main polymer chain is $\alpha(1 \rightarrow 6)$ linked, the repeating unit is *isomaltose*, $\text{Glc}\alpha 1 \rightarrow 6\text{Glc}$. The branch points may be $1 \rightarrow 2$, $1 \rightarrow 3$, or $1 \rightarrow 4$ in various species. The degree of branching and the average chain length between branches depend on the species and strain of the organism. Bacteria growing on the surfaces of teeth produce extracellular accumulations of dextrans, an important component of *dental plaque*.

7.4d Polysaccharides Provide Physical Structure and Strength to Organisms

Cellulose The **structural polysaccharides** have properties that are dramatically different from those of the storage polysaccharides, even though the compositions of these two classes are similar. The structural polysaccharide **cellulose** is the most

abundant natural polymer in the world. Found in the cell walls of nearly all plants, cellulose is one of the principal components providing physical structure and strength. The wood and bark of trees are insoluble, highly organized structures formed from cellulose and also from *lignin*. It is awe inspiring to look at a large tree and realize the amount of weight supported by polymeric structures derived from sugars and organic alcohols. Cellulose also has its delicate side, however. **Cotton**, whose woven fibers make some of our most comfortable clothing fabrics, is almost pure cellulose. Derivatives of cellulose have found wide use in our society. **Cellulose acetates** are produced by the action of acetic anhydride on cellulose in the presence of sulfuric acid and can be spun into a variety of fabrics with particular properties, such as softness and sheen. Referred to simply as *acetates*, they have a silky appearance, a luxuriously soft feel, and a deep luster and are used in dresses, lingerie, linings, and blouses.

Cellulose is a linear homopolymer of D-glucose units, just as in α -amylose. The structural difference, which completely alters the properties of the polymer, is that in cellulose the glucose units are linked by $\beta(1 \rightarrow 4)$ -glycosidic bonds, whereas in α -amylose, the linkage is $\alpha(1 \rightarrow 4)$. The conformational difference between these two structures is shown in Figure 7.23. The $\alpha(1 \rightarrow 4)$ -linkage sites of amylose are naturally bent, conferring a gradual turn to the polymer chain, which results in the helical conformation already described (Figure 7.21). The most stable conformation about the $\beta(1 \rightarrow 4)$ linkage involves alternating 180° flips of the glucose units along the chain so that the chain adopts a fully extended conformation, referred to as an **extended ribbon**. Juxtaposition of several such chains permits efficient interchain hydrogen bonding, the basis of much of the strength of cellulose.

The structure of one form of cellulose, determined by X-ray and electron diffraction data, is shown in Figure 7.24. The flattened sheets of the chains lie side by side and are joined by hydrogen bonds. These sheets are laid on top of one another in a way that staggers the chains, just as bricks are staggered to give strength and stability to a wall. Cellulose is extremely resistant to hydrolysis, whether by acid or by the digestive tract amylases described earlier. As a result, most animals (including humans) cannot digest cellulose to any significant degree. Ruminant animals, such as cattle, deer, giraffes, and camels, are an exception because bacteria that live in the rumen (Figure 7.25) secrete the enzyme **cellulase**, a β -glucosidase effective in the hydrolysis of cellulose. The resulting glucose is then metabolized in a fermentation process to the benefit of the host animal. Termites and shipworms (*Teredo navalis*) similarly digest cellulose because their digestive tracts also contain bacteria that secrete cellulase.

Chitin A polysaccharide that is similar to cellulose, both in its biological function and its primary, secondary, and tertiary structure, is **chitin**. Chitin is present in the cell walls of fungi and is the fundamental material in the exoskeletons of crustaceans, insects, and spiders. The structure of chitin, an extended ribbon, is identical to that of cellulose, except that the $-\text{OH}$ group on each C-2 is replaced by $-\text{NHCOCH}_3$, so the repeating units are **N-acetyl-D-glucosamines** in $\beta(1 \rightarrow 4)$ linkage. Like cellulose (Figure 7.24), the chains of chitin form extended ribbons (Figure 7.26) and

Figure 7.23 The structures of amylose and cellulose. (a) Amylose, composed exclusively of the relatively bent $\alpha(1 \rightarrow 4)$ linkages, prefers to adopt a helical conformation, whereas (b) cellulose, with $\beta(1 \rightarrow 4)$ -glycosidic linkages, can adopt a fully extended conformation with alternating 180° flips of the glucose units. The hydrogen bonding inherent in such extended structures is responsible for the great strength of tree trunks and other cellulose-based materials.

Figure 7.24 The structure of cellulose, showing the hydrogen bonds (blue) between the sheets, which strengthen the structure. Intrachain hydrogen bonds are in red, and interchain hydrogen bonds are in green.

Figure 7.26 Cellulose, chitin and mannan form extended ribbons and pack together efficiently, taking advantage of multiple hydrogen bonds.

Figure 7.25 Giraffes, cattle, deer, and camels are ruminant animals that are able to metabolize cellulose, thanks to bacterial cellulase in the rumen, a large first compartment in the stomach of a ruminant.

pack side by side in a crystalline, strongly hydrogen-bonded form. One significant difference between cellulose and chitin is whether the chains are arranged in **parallel** (all the reducing ends together at one end of a packed bundle and all the nonreducing ends together at the other end) or **antiparallel** (each sheet of chains with the chains arranged oppositely from the sheets above and below). Natural cellulose seems to

A Deeper Look

Ruth Benerito and Wrinkle-Free Cotton Fabrics

Cotton, which is usually 94% cellulose, is the natural fiber most commonly used for clothing. Ordinary cotton fabrics are comfortable and easily dyed, but they wrinkle easily. Permanent press fabrics made from a combination of synthetic resin and cotton fibers appeared in 1932, but these fabrics were less comfortable than pure cotton fabrics.

In the 1950s, chemist Ruth Benerito at the U.S. Agricultural Research Service in New Orleans began experimenting with crosslinking reactions that joined cellulose chains covalently (see figure).

Benerito's work revolutionized the cotton fabric industry, and today this reaction is the basis for more than 80% of "wrinkle-free"

and "permanent press" cotton fabrics. Fabrics made with this process release small amounts of formaldehyde over time, and concerns about safety have prompted the development of new crosslinking processes that produce formaldehyde-free products.

Strands of cellulose can be cross-linked with reagents like Dimethylol dihydroxy ethylene urea (DMDHEU).

occur only in parallel arrangements. Chitin, however, can occur in three forms, sometimes all in the same organism. α -Chitin is an all-parallel arrangement of the chains, whereas β -chitin is an antiparallel arrangement. In δ -chitin, the structure is thought to involve pairs of parallel sheets separated by single antiparallel sheets.

Chitin is the Earth's second most abundant carbohydrate polymer (after cellulose), and its ready availability and abundance offer opportunities for industrial and commercial applications. Chitin-based coatings can extend the shelf life of fruits, and a chitin derivative that binds to iron atoms in meat has been found to slow the reactions that cause rancidity and flavor loss. Without such a coating, the iron in meats activates oxygen from the air, forming reactive free radicals that attack and oxidize polyunsaturated lipids, causing most of the flavor loss associated with rancidity. Chitin-based coatings coordinate the iron atoms, preventing their interaction with oxygen.

Agarose An important polysaccharide mixture isolated from marine red algae (*Rhodophyceae*) is **agar**, which consists of two components: **agarose** and **agarpectin**. Agarose (Figure 7.27) is a chain of alternating D-galactose and 3,6-anhydro-L-galactose, with side chains of 6-methyl-D-galactose. Agarpectin is similar, but in addition, it contains sulfate ester side chains and D-glucuronic acid. The three-dimensional structure of agarose is a double helix with a threefold screw axis, as shown in Figure 7.27. The central cavity is large enough to accommodate water molecules. Agarose and agarpectin readily form gels containing large amounts (up to 99.5%) of water. Agarose gels are used in laboratories to separate macromolecules on the basis of size.

Figure 7.27 The favored conformation of agarose in water is a double helix with a left-handed threefold screw axis (the structure is identical at every 120 degrees of rotation).

Glycosaminoglycans A class of polysaccharides known as **glycosaminoglycans** is involved in a variety of extracellular (and sometimes intracellular) functions. Glycosaminoglycans consist of linear chains of repeating disaccharides in which one of the monosaccharide units is an amino sugar and one (or both) of the monosaccharide units contains at least one negatively charged sulfate or carboxylate group. The repeating disaccharide structures found commonly in glycosaminoglycans are shown in Figure 7.28. Glycosaminoglycans are components of **proteoglycans**. **Heparin**, with the highest net negative charge of the disaccharides shown, is a natural anticoagulant substance. It binds strongly to *antithrombin III* (a protein involved in terminating the clotting process) and inhibits blood clotting. **Hyaluronate** molecules may consist of as many as 25,000 disaccharide units, with molecular weights of up to 10^7 . Hyaluronates are important components of the vitreous humor in the eye and of *synovial fluid*, the lubricant fluid of joints in the body. **Chondroitin** and **keratan sulfate** are found in tendons, cartilage, and other connective tissue; **dermatan sulfate**, as its name implies, is a component of the extracellular matrix of skin. Glycosaminoglycans are fundamental constituents of *proteoglycans* (discussed later).

7.4e Polysaccharides Provide Strength and Rigidity to Bacterial Cell Walls

Some of nature's most interesting polysaccharide structures are found in *bacterial cell walls*. Given the strength and rigidity provided by polysaccharide structures, it is not surprising that bacteria use such structures to provide protection for their cellular contents. Bacteria normally exhibit high internal osmotic pressures and frequently encounter variable, often hypotonic, exterior conditions. The rigid cell walls synthesized

Figure 7.28 Glycosaminoglycans are formed from repeating disaccharide arrays.

A Deeper Look

A Complex Polysaccharide in Red Wine—The Strange Story of Rhamnogalacturonan II

For many years, cotton and grape growers and other farmers have known that boron is an essential trace element for their crops. Until recently, however, the role or roles of boron in sustaining plant growth were unknown. Recent reports show that at least one role for boron in plants is that of cross-linking an unusual polysaccharide called rhamnogalacturonan II (RGII). RGII is a low-molecular-weight (5 to 10 kDa) polysaccharide, but it is thought to be the most complex polysaccharide on Earth, composed as it is of 11 different sugar monomers. It can be released from plant cell walls by treatment with a galacturonase, and it is also present in red wine. A liter of red wine typically contains about 100–150 mg of RG II. Part of the structure of RGII is shown in the accompanying figure. The nature of the borate ester cross-links (also indicated in the figure) was elucidated by Malcolm O'Neill and his colleagues, who used a combination of chemical methods and boron-11 NMR.

Why is rhamnogalacturonan II essential for the structure and growth of plant walls? Plant walls are extremely sophisticated composite materials, composed of networks of protein, polysaccharides, and phenolic compounds. Cellulose microfibrils as strong as steel provide a load-bearing framework for the plant. These microfibrils are tiny wires made of crystalline arrays of $\beta(1 \rightarrow 4)$ -linked chains of glucose residues, which are extruded from hexameric spinnerets in the plasma membrane of the plant

cell, surrounding the growing plant cell like hoops around a barrel. These microfibrils thus constrain the directions of cell expansion and determine the shapes of the plant cells and the plant as well. The separation of the barrel hoops is controlled by hemicelluloses, such as xyloglucans, which form H-bonded crosslinks with the cellulose microfibrils. The hemicellulose network is embedded in a hydrated gel inside the plant wall. This gel consists of complex galacturonic acid-rich polysaccharides, including RGII. The gel provides a dynamic operating environment for cell wall processes.

It is interesting to note that the tiny spinnerets of plant cells are nature's version of the viscose process, developed in 1910, for the production of rayon fibers. In this process, viscose—literally a *viscous* solution of cellulose—is forced through a spinneret (a device resembling a shower head with many tiny holes). Each hole produces a fine filament of viscose. The fibers precipitate in an acid bath and are stretched, resulting in the formation of interchain H bonds that give the filaments the properties essential for use as textile fibers.

Rhamnogalacturonan II (RGII) forms dimers linked by boron atoms to sustain plant growth.

by bacteria maintain cell shape and size and prevent swelling or shrinkage that would inevitably accompany variations in solution osmotic strength.

Bacteria are conveniently classified as either **gram-positive** or **gram-negative**, depending on their response to Gram staining, which identifies multilayered peptidoglycan structures. Despite substantial differences in the various structures surrounding these two types of cells, nearly all bacterial cell walls have a strong, protective peptide–polysaccharide layer called **peptidoglycan**. Gram-positive bacteria have a thick (approximately 25 nm) cell wall consisting of multiple layers of peptidoglycan. This thick cell wall surrounds the bacterial plasma membrane. Gram-negative bacteria, in contrast, have a much thinner (2 nm to 3 nm) cell wall consisting of a single layer of peptidoglycan sandwiched between the inner and outer lipid bilayer membranes. In either case, peptidoglycan, sometimes called **murein** (from the Latin *murus*, meaning “wall”), is a continuous crosslinked structure—in essence, a single molecule—built around the cell. The structure is shown in Figure 7.29. The backbone is a $\beta(1 \rightarrow 4)$ -linked polymer of *N*-acetylglucosamine and *N*-acetylmuramic acid units. This part of the structure is similar to that of chitin, but it is joined to a tetrapeptide, usually L-Ala · D-Glu · L-Lys · D-Ala, in which the L-lysine is linked to the γ -COOH of D-glutamate. The peptide is linked to the *N*-acetylmuramic acid

Figure 7.29 The structure of peptidoglycan. (a) The tetrapeptides linking adjacent backbone chains contain an unusual γ -carboxyl linkage. (b) The crosslink in gram-positive cell walls is a pentaglycine bridge. (c) In gram-negative cell walls, the linkage between the tetrapeptides of adjacent carbohydrate chains in peptidoglycan involves a direct amide bond between the lysine side chain of one tetrapeptide and D-alanine of the other.

units via its D-lactate moiety. The ϵ -amino group of lysine in this peptide is linked to the —COOH of D-alanine of an adjacent tetrapeptide. In gram-negative cell walls, the lysine ϵ -amino group forms a *direct amide bond* with this D-alanine carboxyl (Figure 7.29). In gram-positive cell walls, a **pentaglycine chain** bridges the lysine ϵ -amino group and the D-Ala carboxyl group. Gram-negative cell walls are also covered with highly complex lipopolysaccharides (Figure 7.30).

Cell Walls of Gram-Negative Bacteria In gram-negative bacteria, the peptidoglycan wall is the rigid framework with an elaborate membrane structure around it (Figure 7.30). The peptidoglycan layer encloses the *periplasmic space* and is attached to the outer membrane via a group of *hydrophobic proteins*.

As shown in Figure 7.31, the outer membrane of gram-negative bacteria is coated with a highly complex **lipopolysaccharide**, which consists of a lipid group (anchored in the outer membrane) joined to a polysaccharide made up of long chains with characteristic repeating structures (Figure 7.31). Its many different unique units determine the antigenicity of the

Figure 7.30 The structures of the cell wall and membrane(s) in gram-positive and gram-negative bacteria. The gram-positive cell wall is thicker than that in gram-negative bacteria, compensating for the absence of a second (outer) bilayer membrane.

Figure 7.31 Lipopolysaccharide (LPS) coats the outer membrane of gram-negative bacteria. The lipid portion of the LPS is embedded in the outer membrane and is linked to a complex polysaccharide.

bacteria; that is, animal immune systems recognize them as foreign substances and raise antibodies against them. As a group, these **antigenic determinants** are called the **O antigens**, and there are thousands of different ones. The *Salmonella* bacteria alone have well over a thousand known O antigens that have been organized into 17 different groups. The great variation in these O antigen structures apparently plays a role in the recognition of one type of cell by another and in evasion of the host immune system.

Cell Walls of Gram-Positive Bacteria In gram-positive bacteria, the cell exterior is less complex than for gram-negative cells. Having no outer membrane, gram-positive cells compensate with a thicker wall. Covalently attached to the peptidoglycan layer are **teichoic acids**, which often account for 50% of the dry weight of the cell wall. The teichoic acids are polymers of *ribitol phosphate* or *glycerol phosphate* linked by phosphodiester bonds.

7.4f Animals Display a Variety of Cell Surface Polysaccharides

Compared to bacterial cells, which are identical within a given cell type (except for O antigen variations), animal cells display a wondrous diversity of structure, constitution, and function. Although each animal cell contains in its genetic material the instructions to replicate the entire organism, each differentiated animal cell carefully controls its composition and behavior within the organism. A great part of each cell's uniqueness begins at the cell surface. This surface uniqueness is critical to each animal cell because cells spend their entire life span in intimate contact with other cells and must therefore communicate with one another. That cells are able to pass information among themselves is evidenced by numerous experiments. For example, heart *myocytes*, when grown in culture (in glass dishes), establish *synchrony* when they make contact, so that they beat or contract in unison. If they are removed from the culture and separated, they lose their synchronous behavior, but if allowed to reestablish cell-to-cell contact, they spontaneously restore their synchronous contractions.

As these and many other related phenomena show, it is clear that molecular structures on one cell are recognizing and responding to molecules on the adjacent cell or to molecules in the **extracellular matrix**, the complex mix of connective proteins and other molecules that exists outside of and among cells. Many of these interactions involve *glycoproteins* on the cell surface and *proteoglycans* in the extracellular matrix. The information held in these special carbohydrate-containing molecules is not encoded directly in the genes (as with proteins), but is determined instead by expression of the appropriate enzymes that assemble carbohydrate units in a characteristic way on these molecules. Also, by virtue of the several hydroxyl linkages that can be formed with each carbohydrate monomer, these structures are more information-rich than proteins and nucleic acids, which can form only linear polymers (see Section 7.7). A few of these glycoproteins and their unique properties are described in the following sections.

7.5 | What Are Glycoproteins, and How Do They Function in Cells?

Many proteins found in nature are **glycoproteins** because they contain covalently linked oligosaccharide and polysaccharide groups. The list of known glycoproteins includes structural proteins, enzymes, membrane receptors, transport proteins, and immunoglobulins, among others. In most cases, the precise function of the bound carbohydrate moiety is not understood.

7.5a Carbohydrates on Proteins Can Be O-Linked or N-Linked

Carbohydrate groups are linked to polypeptide chains in only a few ways: either via the hydroxyl groups of serine, threonine, or hydroxyllysine residues (in **O-linked saccharides**) (Figure 7.32a) or via the amide nitrogen of an asparagine residue (in **N-linked saccharides**) (Figure 7.32b). The carbohydrate residue linked to the protein in O-linked saccharides is usually an *N*-acetylgalactosamine, but mannose, galactose, and xylose residues linked to

(a) O-linked saccharides

(b) Core oligosaccharides in N-linked glycoproteins

(c) N-linked glycoproteins

Figure 7.32 The carbohydrate moieties of glycoproteins may be linked to the protein via (a) serine or threonine residues (in the O-linked saccharides) or (b) asparagine residues (in the N-linked saccharides). (c) N-linked glycoproteins are of three types: high mannose, complex, and hybrid, the latter of which combines structures found in the high mannose and complex saccharides.

protein hydroxyls are also found (Figure 7.32a). Oligosaccharides O-linked to glycophorin involve *N*-acetylgalactosamine linkages and are rich in sialic acid residues. N-linked saccharides always have a unique core structure composed of two *N*-acetylglucosamine residues linked to a branched mannose triad (Figure 7.32b, c). Many other sugar units may be linked to each of the mannose residues of this branched core.

7.5b O-GlcNAc Signaling Is Altered in Diabetes and Cancer

O-linked β -*N*-acetylglucosamine (O-GlcNAc) linked to serine or threonine (Figure 7.32a) on nuclear and cytoplasmic proteins serves as a cellular signal, much like phosphorylation at Ser and Thr. O-GlcNAcylation is an abundant, ubiquitous, and dynamic post-translational modification. Proteins modified with O-GlcNAc groups serve as nutrient sensors, both independently and in concert with other post-translational modifications, to regulate transcription, translation, cytoskeletal assembly, signal transduction, and cellular metabolism. Interestingly, O-GlcNAc signaling and its interaction with phosphorylation are both altered in the major diseases of aging, including diabetes, cancer, Alzheimer's, and cardiovascular disease.

7.5c O-Linked Saccharides Form Rigid Extended Extracellular Structures

O-linked saccharides are often found in cell surface glycoproteins and in **mucins**, the large glycoproteins that coat and protect mucous membranes in the respiratory and gastrointestinal tracts in the body. Certain viral glycoproteins also contain O-linked sugars. O-linked saccharides in glycoproteins are often found clustered in richly glycosylated domains of the polypeptide chain. Physical studies on mucins show that they adopt rigid, extended structures. An individual mucin molecule ($M_r = 10^7$) may extend over a distance of 150 nm to 200 nm in solution. Inherent steric interactions between the sugar residues and the protein residues in these cluster regions cause the peptide core to adopt an extended and relatively rigid conformation. This interesting effect may be related to the function of O-linked saccharides in glycoproteins. It allows aggregates of mucin molecules to form extensive, intertwined networks, even at low concentrations. These viscous networks protect the mucosal surface of the respiratory and gastrointestinal tracts from harmful environmental agents.

There appear to be two structural motifs on the extracellular surface of membrane glycoproteins containing O-linked saccharides. Certain glycoproteins, such as **leukosialin**, are O-glycosylated throughout much or most of their extracellular domain (Figure 7.33). Leukosialin, like mucin, adopts a highly extended conformation, allowing it to project great distances above the membrane surface, perhaps protecting the cell from unwanted interactions with macromolecules or other cells. The second structural motif is exemplified by the **low-density lipoprotein (LDL) receptor** and by **decay-accelerating factor (DAF)**. These proteins contain a highly O-glycosylated stem region that separates the transmembrane domain from the globular, functional extracellular domain. The O-glycosylated stem serves to raise the functional domain of the protein far enough above the highly glycosylated membrane surface (a region termed the **glycocalyx**) to make it accessible to the extracellular macromolecules with which it interacts.

7.5d Polar Fish Depend on Antifreeze Glycoproteins

A unique family of O-linked glycoproteins permits fish to live in the icy seawater of the Arctic and Antarctic regions, where water temperature may reach as low as -1.9°C . **Antifreeze glycoproteins (AFGPs)** are found in the blood of nearly all Antarctic fish and at least five Arctic fish. These glycoproteins have the peptide structure

where n can be 4, 5, 6, 12, 17, 28, 35, 45, or 50. Each of the threonine residues is glycosylated with the disaccharide β -galactosyl-(1 $\rightarrow$ 3)- α -*N*-acetylgalactosamine (Figure 7.34). This glycoprotein adopts a *flexible rod* conformation with regions of

Figure 7.33 The O-linked saccharides of glycoproteins appear in many cases to adopt extended conformations that serve to extend the functional domains of these proteins above the membrane surface. (Adapted from Jentoft, N., 1990. Why are proteins O-glycosylated? *Trends in Biochemical Sciences* 15:291–294.)

Figure 7.34 The structure of the repeating unit of antifreeze glycoproteins, a disaccharide consisting of β -galactosyl-(1 $\rightarrow$ 3)- α -N-acetylgalactosamine in glycosidic linkage to a threonine residue.

threefold left-handed helix. The evidence suggests that antifreeze glycoproteins may inhibit the formation of ice in the fish by binding specifically to the growth sites of ice crystals, inhibiting further growth of the crystals.

7.5e N-Linked Oligosaccharides Can Affect the Physical Properties and Functions of a Protein

N-linked oligosaccharides are found in many different proteins, including immunoglobulins G and M, ribonuclease B, ovalbumin, and peptide hormones. Many different functions are known or suspected for N-glycosylation of proteins. N-Glycosylation can affect the physical and chemical properties of proteins, altering solubility, mass,

Human Biochemistry

Drug Research Finds a Sweet Spot

A variety of diseases are being successfully treated with sugar-based therapies. As this table shows, several carbohydrate-based drugs are either on the market or at various stages of clinical trials. Some of these drugs are enzymes, whereas others are glycoconjugates.

Drug	Description	Manufacturer
Tamiflu and Relenza	These “transition state analogs” (see Chapter 14) inhibit neuraminidase, an influenza enzyme that enables new virus particles to bud from a host cell.	GlaxoSmithKline (Relenza) and Genentech (Tamiflu)
Cerezyme (imiglucerase)	This enzyme degrades glycolipids, compensating for an enzyme deficiency that causes Gaucher’s disease.	Genzyme Cambridge, MA
Vancocin (vancomycin)	A very potent glycopeptide antibiotic that is typically used against antibiotic-resistant infections. It inhibits synthesis of peptidoglycan in the bacterial cell wall.	Eli Lilly Indianapolis, IN
GMK	A vaccine containing ganglioside GM2; it triggers an immune response against cancer cells carrying GM2.	Progenics Pharmaceuticals Tarrytown, NY
Bimosiamose (TBC1269)	A sugar analog that inhibits selectin-based inflammation in blood vessels.	Revotar PharmAG, Berlin
GCS-100	A sugar that blocks action of galectin-3 (Gal-3), a sugar-binding protein on tumors.	GlycoGenesys Boston
PI-88	A sugar that inhibits growth factor–dependent angiogenesis and enzymes that promote metastasis.	Progen Darra, Australia
StaphVAX	A vaccine that is a protein with a linked bacterial sugar; it is intended to prevent <i>Staphylococcus</i> infection.	NABI Pharmaceuticals Boca Raton, FL

and electrical charge. Carbohydrate moieties have been shown to stabilize protein conformations and protect proteins against proteolysis. Eukaryotic organisms use post-translational additions of N-linked oligosaccharides to direct selected proteins to various membrane compartments. Recent evidence indicates that N-linked oligosaccharides promote the proper folding of newly synthesized polypeptides in the endoplasmic reticulum.

7.5f Sialic Acid Terminates the Oligosaccharides of Glycoproteins and Glycolipids

The oligosaccharide chains of glycoproteins and glycolipids serve as ligands for mammalian sugar-binding proteins and also as receptors for pathogens such as influenza and polyoma virus, for bacteria, and for bacterial toxins when they bind to

the host cell. The terminal sugars of most such oligosaccharide chains are sialic acids, the most common being Neu5Ac (Figure 7.15), and the sialic acid-capped oligosaccharides themselves are termed **sialosides**. Sialosides on glycoproteins and glycolipids mediate aspects of immune responses and leukocyte trafficking to lymph nodes and inflammation sites, among other functions. The biosynthesis of sialosides is carried out by 20 *sialyltransferase* enzymes that are highly conserved in mammals.

7.5g Sialic Acid Cleavage Can Serve as a Timing Device for Protein Degradation

The slow cleavage of sialic acid residues from N-linked glycoproteins circulating in the blood targets these proteins for normal degradation by the organism. The liver contains specific receptor proteins that recognize and bind glycoproteins that are ready to be degraded and recycled. Newly synthesized serum glycoproteins contain N-linked **triantennary** (three-chain) oligosaccharides with structures similar to those in Figure 7.35, in which sialic acid residues cap galactose residues. As these glycoproteins circulate, enzymes on the blood vessel walls remove the sialic acid groups, exposing the galactose residues. In the liver, the **asialoglycoprotein receptor** binds the exposed galactose residues of these glycoproteins with very high affinity ($K_D = 10^{-9} M$ to $10^{-8} M$). The complex of receptor and glycoprotein is then taken into the cell by *endocytosis*, and the glycoprotein is degraded in cellular lysosomes. Highest affinity binding of glycoprotein to the asialoglycoprotein receptor requires three free galactose residues. Oligosaccharides with only one or two exposed galactose residues bind less tightly. This is an elegant way for the body to keep track of how long glycoproteins have been in circulation. Over a period of time—anywhere from a few hours to weeks—the sialic acid groups are cleaved one by one. The longer the glycoprotein circulates and the more sialic acid residues are removed, the more galactose residues become exposed so that the glycoprotein is eventually bound to the liver receptor.

Figure 7.35 Progressive cleavage of sialic acid residues exposes galactose residues. Binding to the asialoglycoprotein receptor in the liver becomes progressively more likely as more Gal residues are exposed.

7.6 How Do Proteoglycans Modulate Processes in Cells and Organisms?

Proteoglycans are a family of glycoproteins whose carbohydrate moieties are predominantly *glycosaminoglycans*. The structures of only a few proteoglycans are known, and even these few display considerable diversity (Figure 7.36). Those known range in size from *serglycin*, with 104 amino acid residues (10.2 kD), to *versican*, with 2409 residues (265 kD). Each of these proteoglycans contains one or two types of covalently linked glycosaminoglycans. In the known proteoglycans, the glycosaminoglycan units are O-linked to serine residues of Ser-Gly dipeptide sequences. *Serglycin* is named for a unique central domain of 49 amino acids composed of alternating serine and glycine residues. The *cartilage matrix proteoglycan* contains 117 Ser-Gly pairs to which

Figure 7.36 The known proteoglycans include a variety of structures. The carbohydrate groups of proteoglycans are predominantly glycosaminoglycans O-linked to serine residues. Proteoglycans include both soluble proteins and integral transmembrane proteins.

chondroitin sulfates attach. **Decorin**, a small proteoglycan secreted by fibroblasts and found in the extracellular matrix of connective tissues, contains only three Ser-Gly pairs, only one of which is normally glycosylated. In addition to glycosaminoglycan units, proteoglycans may contain other N-linked and O-linked oligosaccharide groups.

7.6a Functions of Proteoglycans Involve Binding to Other Proteins

Proteoglycans may be *soluble* and located in the extracellular matrix, as is the case for serglycin, versican, and the cartilage matrix proteoglycan, or they may be *integral transmembrane proteins*, such as *syndecan*. Both types of proteoglycan appear to function by interacting with a variety of other molecules through their glycosaminoglycan components and through specific receptor domains in the polypeptide itself. For example, syndecan (from the Greek *syndein*, meaning “to bind together”) is a transmembrane proteoglycan that associates intracellularly with the actin cytoskeleton. Outside the cell, it interacts with **fibronectin**, an extracellular protein that binds to several cell surface proteins and to components of the extracellular matrix. The ability of syndecan to participate in multiple interactions with these target molecules allows them to act as a sort of glue in the extracellular space, linking components of the extracellular matrix, facilitating the binding of cells to the matrix, and mediating the binding of growth factors and other soluble molecules to the matrix and to cell surfaces (Figure 7.37).

Many of the functions of proteoglycans involve the binding of specific proteins to the glycosaminoglycan groups of the proteoglycan. The glycosaminoglycan-binding sites on these specific proteins contain multiple basic amino acid residues. The amino acid sequences BBXB and BBBXXB (where B is a basic amino acid and X is any amino acid) recur repeatedly in these binding domains. Basic amino acids such as lysine and arginine provide charge neutralization for the negative charges of glycosaminoglycan residues, and in many cases, the binding of extracellular matrix proteins to glycosaminoglycans is primarily charge dependent. For example, more highly sulfated glycosaminoglycans bind more tightly to fibronectin. However, certain protein–glycosaminoglycan interactions require a specific carbohydrate sequence. A particular pentasaccharide sequence in heparin, for example, binds tightly to antithrombin III (Figure 7.38), accounting for the anticoagulant properties of heparin. Other glycosaminoglycans interact much more weakly.

Figure 7.37 Proteoglycans serve a variety of functions on the cytoplasmic and extracellular surfaces of the plasma membrane. Many of these functions appear to involve the binding of specific proteins to the glycosaminoglycan groups.

Figure 7.38 A portion of the structure of heparin, a carbohydrate having anticoagulant properties. It is used by blood banks to prevent the clotting of blood during donation and storage and also by physicians to prevent the formation of life-threatening blood clots in patients recovering from serious injury or surgery. This sulfated pentasaccharide sequence in heparin binds with high affinity to antithrombin III, accounting for this anticoagulant activity. The 3-O-sulfate marked by an asterisk is essential for high-affinity binding of heparin to antithrombin III.

7.6b Proteoglycans May Modulate Cell Growth Processes

Several lines of evidence support the possibility of modulation or regulation of cell growth processes by proteoglycans. First, heparin and heparan sulfate are known to inhibit cell proliferation in a process involving internalization of the glycosaminoglycan moiety and its migration to the cell nucleus. Second, *fibroblast growth factor* binds tightly to heparin and other glycosaminoglycans, and the heparin–growth factor complex protects the growth factor from degradative enzymes, thus enhancing its activity. Binding of fibroblast growth factors by proteoglycans and glycosaminoglycans in the extracellular matrix creates a reservoir of growth factors for cells to use. Third, *transforming growth factor β* has been shown to stimulate the synthesis and secretion of proteoglycans in certain cells. Fourth, several proteoglycan core proteins, including versican and *lymphocyte homing receptor*, have domains similar in sequence to those of *epidermal growth factor* and *complement regulatory factor*. These growth factor domains may interact specifically with growth factor receptors in the cell membrane in processes that are not yet understood.

7.6c Proteoglycans Make Cartilage Flexible and Resilient

Cartilage matrix proteoglycan is responsible for the flexibility and resilience of cartilage tissue in the body. In cartilage, long filaments of hyaluronic acid are studded or coated with proteoglycan molecules, as shown in Figure 7.39. The hyaluronate chains can be as long as 4 μm and can coordinate 100 or more proteoglycan units. Cartilage proteoglycan possesses a *hyaluronic acid-binding domain* on the NH_2 -terminal portion of the polypeptide, which binds to hyaluronate with the assistance of a *link protein*. The proteoglycan–hyaluronate aggregates can have molecular weights of 2 million or more.

The proteoglycan–hyaluronate aggregates are highly hydrated by virtue of strong interactions between water molecules and the polyanionic complex. When cartilage is compressed (such as when joints absorb the impact of walking or running), water is briefly squeezed out of the cartilage tissue and then reabsorbed when the stress is diminished. This reversible hydration gives cartilage its flexible, shock-absorbing qualities and cushions the joints during physical activities that might otherwise injure the involved tissues.

7.7 | How Do Carbohydrates Provide a Structural Code?

The surprisingly low number of genes in the genomes of complex multicellular organisms has led biochemists to consider other explanations for biological complexity and diversity. Oligosaccharides and polysaccharides, endowed with an unsurpassed variability of structures, are information carriers. Glycoconjugates—complexes of proteins and lipids with oligosaccharides and polysaccharides—are the mediators of information transfer

Figure 7.39 The human knee joint is a marvel of nature's engineering. Proteoglycans in structures in the joint allow it to absorb shock during movements such as walking and running. Articular cartilage slides with extremely low friction against the cushioning meniscus when the knee bends. Articular cartilage is 68–85% water, adsorbed in a network of collagen fibers (10–20%) and proteoglycans (5–10%). The meniscus is also mostly water (70%). The meniscus's dry weight is 75% collagen and 25% proteoglycan. Hyaluronate (see Figure 7.28) forms the backbone of proteoglycan structures, such as those found in cartilage. The proteoglycan subunits consist of a core protein containing numerous O-linked and N-linked glycosaminoglycans. The glycosaminoglycans in the meniscus proteoglycan include chondroitin sulfate (50–60%), dermatan sulfate (20–30%), and keratan sulfate (15%). (See Figure 7.28 for these structures.) In cartilage, these highly hydrated proteoglycan structures are enmeshed in a network of collagen fibers. Release (and subsequent reabsorption) of water by these structures during compression accounts for the shock-absorbing qualities of cartilaginous tissue.

by these carbohydrate structures. Individual sugar units are the letters of the *sugar code*, and the words and sentences of this code are synthesized by glycosyltransferases, glycosidases, and other enzymes. These sentences are read by the binding of proteins to these sugar groups. The total number of permutations for a six-unit polymer formed from an alphabet of 20 hexose monosaccharides is a staggering 1.44×10^{15} , whereas only 6.4×10^7 hexamers can be formed from 20 amino acids and only 4096 hexanucleotides can be formed from the four nucleotides of DNA.

Studies of glycomics have generated vast amounts of information, which is stored and managed in multiple publicly available carbohydrate databases:
<http://www.glycosciences.de/>
<http://www.genome.jp/kegg/glycan/>
<http://functionalglycomics.org/>
http://jicggdb.jp/rcmg/glycodb/Ms_ResultSearch
<https://glytouban.org/>

The covalent addition of glycans to proteins and lipids represents not only the most abundant post-translational modification of proteins, but also the most structurally diverse. Glycoconjugates respond to and control metabolic states and developmental stages of cells, and they are directly involved in almost every biological process and play a major role in nearly every human disease. The vast array of possible glycan structures adds a *glycomic dimension* to the genomic complexity achieved by protein expression in organisms. The glycome is the complete set of glycans and glycoconjugates that are made by a cell or organism under specific conditions, and glycomics refers to studies that attempt to define or quantify the glycome of a cell, tissue, or organism.

Glycan microarray technology, in which dozens or hundreds of complex glycans are immobilized in a resolvable pattern on a solid support, has made it possible to characterize the interactions between particular glycans and their protein- and enzyme-binding partners. The specificities of glycan-binding proteins (GBPs) are determined by comparing binding to all glycans presented on the microarray. More than a thousand GBPs and glycan-processing enzymes are known, and the human glycome is estimated to encompass hundreds of thousands of structures.

7.7a Lectins Translate the Sugar Code

The processes of cell migration, cell–cell interaction, immune response, and blood clotting, along with many other biological processes, depend on information transfer modulated by glycoconjugates. Many of the proteins involved in glycoconjugate formation belong to the **lectins**—a class of proteins that bind carbohydrates with high specificity and affinity. *Lectins are the translators of the sugar code.* Table 7.1 describes a few of the many known lectins, their carbohydrate affinities, and their functions. A few examples of lectin–carbohydrate complexes and their roles in biological information transfer will illustrate the nature of these important and complex interactions.

7.7b Selectins, Rolling Leukocytes, and the Inflammatory Response

Human bodies are constantly exposed to a plethora of bacteria, viruses, and other inflammatory substances. To combat these infectious and toxic agents, the body has developed a carefully regulated inflammatory response system. Part of that response is the orderly migration of leukocytes (a class of white blood cells) to sites of inflammation. Leukocytes roll along the vascular wall and into the tissue site of inflammation. This rolling movement is mediated by reversible adhesive interactions between the leukocytes and the vascular surface.

These interactions involve adhesion proteins called **selectins**, which are found both on the rolling leukocytes and on the endothelial cells of the vascular walls. Selectins have a characteristic domain structure, consisting of an N-terminal extracellular lectin (LEC) domain, a single epidermal growth factor (E) domain, a series of two to nine

Table 7.1 Specificities and Functions of Some Animal Lectins		
Lectin Family	Carbohydrate Specificity	Function
Calnexins	Glucose	Ligand-selective molecular chaperones in ER
C-type lectins	Variable	Cell-type specific endocytosis and other functions
ERGIC-53	Mannose	Intracellular routing of glycoproteins and vesicles
Galectins	Galactose/lactose	Cellular growth regulation and cell–matrix interactions
Pentraxins	Variable	Anti-inflammatory action
Selectins	Variable	Cell migration and routing

short consensus repeat (SCR) domains, a single transmembrane segment, and a short cytoplasmic domain. The lectin domains bind carbohydrates with high affinity and specificity. Selectins of three types are known: E-selectins, L-selectins, and P-selectins. L-Selectin is found on the surfaces of leukocytes, including neutrophils and lymphocytes, and binds to carbohydrate ligands on endothelial cells (Figure 7.40). The presence of L-selectin is a necessary component of leukocyte rolling. P-Selectin and E-selectin are located on the vascular endothelium and bind with carbohydrate ligands on leukocytes. Typical neutrophil cells possess 10,000 to 20,000 P-selectin-binding sites. Selectins are expressed on the surfaces of their respective cells by exposure to inflammatory signal molecules, such as histamine, hydrogen peroxide, and bacterial endotoxins. P-Selectins, for example, are stored in intracellular granules and are transported to the cell membrane within seconds to minutes of exposure to a triggering agent.

Substantial evidence supports the hypothesis that selectin-carbohydrate ligand interactions modulate the rolling of leukocytes along the vascular wall. Studies with L-selectin-deficient and P-selectin-deficient leukocytes show that L-selectins mediate weaker adherence of the leukocyte to the vascular wall and promote faster rolling along the wall. Conversely, P-selectins promote stronger adherence and slower rolling. Thus, leukocyte rolling velocity in the inflammatory response could be modulated by variable exposure of P-selectins and L-selectins at the surfaces of endothelial cells and leukocytes, respectively.

7.7c Galectins—Mediators of Inflammation, Immunity, and Cancer

The galectins are a highly conserved family of proteins with carbohydrate recognition domains (CRDs) of about 135 amino acids that bind β -galactosides specifically. Galectins occur in both vertebrates and invertebrates, and they participate in processes such as cell adhesion, growth regulation, inflammation, immunity, and cancer metastasis. In humans, one galectin is associated with increased risk of heart attacks and another is implicated in inflammatory bowel disease. Human galectin-1 is a dimer of antiparallel beta-sandwich subunits (Figure 7.41). Lactose binds at opposite ends of the dimer. Structural studies of the protein in the presence and absence of ligand reveal that the amino acid residues implicated in galactose binding are kept in their proper orientation in the absence of ligand by a hydrogen-bonded network of four water molecules.

Figure 7.40 Selectins. **(a)** The interactions of selectins with their receptors. **(b)** The selectin family of adhesion proteins.

Figure 7.41 Structure of the human galectin-1 dimer. The lactose-binding sites are at opposite ends of the dimer. (PDB id = 1W6O)

Figure 7.42 C-reactive protein is a lectin that limits inflammation damage. **(a)** The C-reactive protein pentamer. **(b)** The phosphocholine-binding site of C-reactive protein contains two bound Ca^{2+} ions (orange) and a hydrophobic pocket. Phe⁶⁶ is shown in yellow. (PDB id = 1B09)

C-reactive protein belongs to a protein family called pentraxins. These lectins adopt an unusual quaternary structure in which five identical subunits combine to form a planar ring with a central hole (Figure 7.42a). C-reactive protein functions to limit tissue damage, acute inflammation, and autoimmune reactions. C-reactive protein acts by binding to phosphocholine moieties on damaged membranes. A CRP (C-reactive protein) test can be used to determine the risk of developing coronary artery disease. Binding of the protein to phosphocholine is apparently mediated through a bound calcium ion and a hydrophobic pocket centered on Phe⁶⁶ (Figure 7.42b).

Foundational Biochemistry Things You Should Know after Reading Chapter 7.

- Carbohydrates have the molecular formula $(\text{CH}_2\text{O})_n$.
- Carbohydrates are the metabolic precursors to virtually all other biomolecules and the breakdown of carbohydrates provides energy that sustains animal life.
- Carbohydrates contain at least one, and often two or more, asymmetric centers and may exist in linear or cyclic forms.
- Monosaccharides may be described as aldoses and ketoses, or as trioses, tetroses, pentoses, and hexoses. Cyclic forms may be described as furanoses and pyranoses.
- Stereoisomers that are nonsuperimposable mirror images of each other are enantiomers.
- Stereoisomers that have opposite configurations at one or more chiral centers, but that are not mirror images of each other, are diastereomers.
- Sugars that differ in configuration at only one chiral center are epimers.
- When hemiacetals and hemiketals are formed from simple sugars, the carbon atom that carried the carbonyl function becomes an asymmetric carbon and is known as the anomeric carbon.
- Monosaccharides can be converted to several derivative forms, including sugar acids, sugar alcohols, deoxy sugars, sugar esters, and amino sugars.
- The furanose and pyranose forms of monosaccharides react with alcohols to form glycosides. The new bond between the anomeric carbon and the oxygen atom of the alcohol is called a glycosidic bond.
- Short polymers of simple sugars are known as oligosaccharides.
- The end of an oligosaccharide (or polysaccharide) with an unsubstituted anomeric carbon is known as a reducing end. Ends of oligo- and polysaccharides that do not contain an unsubstituted anomeric carbon are known as nonreducing ends.
- Polysaccharides that contain only one kind of monosaccharide are termed homopolysaccharides. Polysaccharides that contain two or more kinds of monosaccharides are known as heteropolysaccharides.
- Starch, glycogen, and dextrans are storage polysaccharides. Amylose and amylopectin are composed of linear chains of D-glucose in $\alpha(1\rightarrow4)$ linkages. The branches in amylopectin and glycogen are $\alpha(1\rightarrow6)$ linkages. The main polymer chain of dextrans consists of $\alpha(1\rightarrow6)$ linkages, whereas the branches are $1\rightarrow2$, $1\rightarrow3$, or $1\rightarrow4$.
- Cellulose is a structural polysaccharide consisting of chains of D-glucose with $\beta(1\rightarrow4)$ linkages.
- Glycosaminoglycans consist of linear chains of repeating disaccharides in which one of the monosaccharide units is an amino sugar and one or both contain at least one negative charge.
- Gram-positive bacteria have a thick cell wall consisting of multiple layers of peptidoglycan. Gram-negative bacteria have a thin peptidoglycan layer sandwiched between two lipid bilayers.
- O-linked saccharides of glycoproteins typically form rigid extended extracellular structures.
- N-linked saccharides of glycoproteins affect the physical and chemical properties of proteins, stabilizing protein conformations, protecting against proteolysis, and promoting proper folding of newly synthesized polypeptides.
- Proteoglycans, glycoproteins whose carbohydrate moieties are mostly glycosaminoglycans, modulate a variety of processes in cells and organisms.
- Oligosaccharides and polysaccharides are information carriers that are directly involved in almost every biological process and play a major role in many human diseases.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. **Drawing Haworth Structures of Sugars** Draw Haworth structures for the two possible isomers of D-altrose (Figure 7.2) and D-psicose (Figure 7.3).
2. **Drawing the Structure of a Glycopeptide** (Integrates with Chapters 4 and 5.) Consider the peptide DGNILSR, where N has a covalently linked galactose and S has a covalently linked glucose. Draw the structure of this glycopeptide, and also draw titration curves for the glycopeptide and for the free peptide that would result from hydrolysis of the two sugar residues.
3. Draw the structures of all the possible epimers of D-arabinose (Figure 7.2).
4. Draw the structures of all the possible diastereomers of D-xylose (Figure 7.2) that are D-sugars.
5. If the configuration at C-5 of D-mannose is changed, the molecule becomes an L-sugar, but it is not L-mannose. Instead it becomes the L-enantiomer of what sugar? (Compare the aldohexose structures in Figure 7.2 to determine the answer.)
6. The distinction between configuration and conformation was described in Section 5.1d.
 - a. Consider D-galactose and D-talose (Figure 7.2). Do these molecules represent different configurations or different conformations? Explain.

- b. Draw the two possible chair structures of β -D-allose. Do these structures represent two configurations or two conformations? Explain.
7. Draw the structure of D-2-deoxyribose. Which other D-2-deoxyaldopentose would have the same structure as D-2-deoxyribose? (Compare the aldopentose structures in Figure 7.2 to determine the answer.)
 8. The ketone group of fructose cannot be oxidized without decomposition of the sugar, yet fructose is considered to be a reducing sugar. Explain. (Hint: fructose can undergo tautomerizations.)
 9. **Naming and Characterizing a Disaccharide** Trehalose, a disaccharide produced in fungi, has the following structure:

- a. What is the systematic name for this disaccharide?
 - b. Is trehalose a reducing sugar? Explain.
10. **Drawing the Fischer Projection of a Simple Sugar** Draw a Fischer projection structure for L-sorbose (D-sorbose is shown in Figure 7.3).

- 11. Linked Carbohydrates** Consider the structure shown and give the proper description of the linkage from A to B.

- 12. Conversion of Fisher Projection into Haworth Projection** Consider the structure shown. Draw the Haworth projection for the corresponding β -pyranose of this carbohydrate.

- 13. Epimers-Anomers-Enantiomers** Consider the structure shown and draw its anomer, enantiomer, and C3 epimer.

- 14. Carbohydrate Classification** Consider the structures shown. For each structure select all descriptions that apply. Is it a pentose, hexose, or heptose? D or L? Ketose or aldose? α or β ? Pyranose or furanose?

Structure A

Structure B

Structure C

- 15. Calculating the Composition of Anomeric Sugar Mixtures** α -D-Glucose has a specific rotation, $[\alpha]_D^{20}$, of $+112.2^\circ$, whereas β -D-glucose has a specific rotation of $+18.7^\circ$. What is the composition of a mixture of α -D- and β -D-glucose, which has a specific rotation of 83.0° ?

- 16. Naming Sugars in the (R,S) System** Use the information in the Critical Developments in Biochemistry box titled "Rules for Description of Chiral Centers in the (R,S) System" (Chapter 4) to name D-galactose using (R,S) nomenclature. Do the same for L-altrose.

- 17. Determining the Branch Points and Reducing Ends of Amylopectin** A 0.2 g sample of amylopectin was analyzed to determine the fraction of the total glucose residues that are branch points in the

structure. The sample was exhaustively methylated and then digested, yielding $50 \mu\text{mol}$ of 2,3-dimethylglucose and $0.4 \mu\text{mol}$ of 1,2,3,6-tetramethylglucose.

- What fraction of the total residues are branch points?
- How many reducing ends does this sample of amylopectin have?

- 18. The Effect of Carbohydrates on Proteolysis of Glycophorin** (Integrates with Chapters 5, 6, and 9.) Consider the sequence of glycophorin (see Figure 9.10), and imagine subjecting glycophorin, and also a sample of glycophorin treated to remove all sugars, to treatment with trypsin and chymotrypsin. Would the presence of sugars in the native glycophorin make any difference to the results?

- 19. Assessing the Caloric Content of Protein and Carbohydrate** (Integrates with Chapters 4, 5, and 23.) The caloric content of protein and carbohydrate are quite similar, at approximately 16 to 17 kJ/g, whereas that of fat is much higher, at 38 kJ/g. Discuss the chemical basis for the similarity of the values for carbohydrate and for protein.

- 20. Writing a Mechanism for Starch Phosphorylase** Write a reasonable chemical mechanism for the starch phosphorylase reaction (Figure 7.22).

- 21. Assessing the Toxicity of Laetrile** Laetrile is a glycoside found in bitter almonds and peach pits. Laetrile treatment is offered in some countries as a cancer therapy. This procedure is dangerous, and there is no valid clinical evidence of its efficacy. Look up the structure of laetrile and suggest at least one reason that laetrile treatment could be dangerous for human patients.

- 22. Assessing the Efficacy of Glucosamine and Chondroitin for Arthritis Pain** Treatment with chondroitin and glucosamine is offered as one popular remedy for arthritis pain. Suggest an argument for the efficacy of this treatment, and then comment on its validity, based on what you know of polysaccharide chemistry.

- 23. Assessing a Remedy for Flatulence** Certain foods, particularly beans and legumes, contain substances that are indigestible (at least in part) by the human stomach, but which are metabolized readily by intestinal microorganisms, producing flatulence. One of the components of such foods is stachyose.

Stachyose

Beano is a commercial product that can prevent flatulence. Describe the likely breakdown of stachyose in the human stomach and intestines and how Beano could contribute to this process. What would be an appropriate name for the active ingredient in Beano?

- 24. Determining the Systematic Name for a Trisaccharide** Give the systematic name for stachyose.

- 25. Assessing the Formation and Composition of Limit Dextrins** Prolonged exposure of amylopectin to starch phosphorylase yields a substance called a limit dextrin. Describe the chemical composition

- of limit dextrins, and draw a mechanism for the enzyme-catalyzed reaction that can begin the breakdown of a limit dextrin.
26. **Assessing the Chemistry and Enzymology of “Light Beer”** Biochemist Joseph Owades revolutionized the production of beer in the United States by developing a simple treatment with an enzyme that converted regular beer into “light beer,” which was marketed aggressively as a beverage that “tastes great,” even though it is “less filling.” What was the enzyme-catalyzed reaction that Owades used to modify the fermentation process so cleverly, and how is regular beer different from light beer?
 27. **Brewing “Light Beer” on a Budget** Amateur brewers of beer, who do not have access to the enzyme described in Problem 26, have nonetheless managed to brew light beers using a readily available commercial product. What is that product, and how does it work?
 28. **Assessing the Growth Potential and Enzymology of a Prolific Plant Nuisance** Kudzu is a vine that grows prolifically in the southern and southeastern United States. A native of Japan, China, and India, kudzu was brought to the United States in 1876 at the Centennial Exposition in Philadelphia. During the Great Depression of the 1930s, the Soil Conservation Service promoted kudzu for erosion control, and farmers were paid to plant it. Today, however, kudzu is a universal nuisance, spreading rapidly, and covering and destroying trees in large numbers. Already covering 7 to 10 million acres in the United States, kudzu grows at the rate of a foot per day. Assume that the kudzu vine consists almost entirely of cellulose fibers, and assume that the fibers lie parallel to the vine axis. Calculate the rate of the cellulose synthase reaction that adds glucose units to the growing cellulose molecules. Use the structures in your text to make a reasonable estimate of the unit length of a cellulose molecule (from one glucose monomer to the next).
 29. Lactaid is a commercial product that mitigates intestinal distress for individuals who are lactose intolerant. What is the active ingredient in Lactaid that accounts for its beneficial effects?
 30. Lactaid milk is available in most grocery stores. It is regular milk from which the lactose sugar has been removed. How is Lactaid milk prepared commercially? Is the lactose sugar separated from the milk, or could there be another way to produce it? How could a clever biochemistry student accomplish this at home? Consult appropriate online resources to learn more:
<https://www.fodmapeveryday.com/diy-lactose-free-dairy/>
 and
<https://www.lacteeze.com.au/about-lacteeze/how-does-lacteeze-help/>.
 31. It is estimated that one-third of the proteins encoded by the mammalian genome are made at and then exported from the endoplasmic reticulum, and nearly all of these are glycosylated at asparagine residues. The N-linked oligosaccharides on these proteins are said to enhance solubility and folding via what are termed *intrinsic* and *extrinsic* effects. Consult a suitable reference (for example, Hebert, D. N., Lamriben, L., Powers, E. T., and Kelly, J. W., 2014. The intrinsic and extrinsic effects of N-linked glycans on glycoproteostasis. *Nature Chemical Biology* 10:902–910) and describe the detailed nature of these intrinsic and extrinsic effects on protein solubility and folding.
 32. The plant family *Cucurbitaceae* includes melons, cucumbers, and pumpkins, all of which produce particularly large fruits. Growth of such large fruits depends on a transport system that can deliver the products of photosynthesis—sugars and other nutrients—from the leaves through the stem and into the sink tissues, such as the fruits and roots, where they are used in growth and storage. The phloem is the living tissue that is responsible for this transport. Consult suitable references (for example, Turgeon, R., and Oparka, K., 2010. The secret phloem of pumpkins. *Proceedings of the National Academy of Sciences* 107:13201–13202) to learn:
 - a. Which part of the phloem is primarily responsible for transport of nutrients,
 - b. what is the concentration of sugars in this phloem that enables the growth of large fruits like pumpkins, and
 - c. what is the polysaccharide that is deposited at the site of tissue damage in such plants?
 - d. Draw the two kinds of sugar–sugar linkages found in this polysaccharide.
 33. Lewis-a trisaccharide is a fucosyloligosaccharide present in human milk and colostrum, which is important for the protection of infants against infection by pathogenic microorganisms. Lewis-a trisaccharide is found on the surface of erythrocytes and is a tumor-related antigen. It is an amino trisaccharide consisting of N-acetylglucosamine having a fucosyl residue attached at the 4-position via an α -linkage and a galactosyl residue attached at the 3-position via a β -linkage. Draw the structure of this trisaccharide.
 34. The human mannose receptor is expressed on macrophages and on liver endothelial cells. It acts to scavenge lysosomal proteins, glycopeptide fragments of collagen, and pathogenic organisms. The receptor binds fucose, mannose, and N-acetylglucosamine residues on these target proteins, mainly via interactions with a Ca^{2+} ion on the CRD4 domain of the receptor. Glycan microarray screening has been used recently to identify the preferred oligosaccharide ligands of the receptor (Feinberg, H., Jegouzo, S., Lasanajak, Y., et al., 2021. Structural analysis of carbohydrate binding by the macrophage mannose receptor CD206. *J. Biol. Chem.* 296:100368.) Consult this reference, summarize the results of the glycan microarray screening, describe the domain structure of the mannose receptor, and describe the details of the interaction of mannose and fucose ligands with the Ca^{2+} ion in the CRD4 domain.
 35. Heparin has a characteristic pattern of hydroxy and anionic functions. Which amino acid side chains on antithrombin III might be the basis for the strong interactions between this protein and the anticoagulant heparin?
 36. What properties of hyaluronate, chondroitin sulfate, and keratan sulfate make them ideal components of cartilage?
 37. Use a suitable molecular graphics software package (PyMOL, JSmol, or ICM-Browser – all available as free downloads) to study and describe the C-reactive protein complexed with phosphocholine (Figure 7.42, PDB id = 1B09). What are the residues that coordinate the phosphocholine? What are the interactions that facilitate the formation of the pentamer structure?
 38. Use a suitable molecular graphics software package (PyMOL, JSmol, or ICM-Browser – all available as free downloads) to study and describe the galectin-1 dimer (Figure 7.41, PDB id = 1W6O). What are the hydrophobic residues at the dimer interface that facilitate dimer formation? What are the residues that coordinate the bound lactose?

Essential Question

Lipids are a class of biological molecules defined by low solubility in water and high solubility in nonpolar solvents. Lipid molecules are key components of membranes and also serve a myriad of roles as signal molecules in biological systems. **What are the structure, chemistry, and biological function of lipids?**

Lipids are largely hydrocarbon in nature. They consist of highly reduced forms of carbon and, upon oxidation in metabolism, yield large amounts of energy. Lipids are thus the molecules of choice for metabolic energy storage. Lipids are integrators of cellular function and intercellular communication. Lipid–lipid and lipid–protein interactions regulate cellular physiology. The lipids found in biological systems are either **hydrophobic** (containing only nonpolar groups) or **amphipathic** (possessing both polar and nonpolar groups). The hydrophobic nature of lipid molecules allows membranes to act as effective barriers to more polar molecules. In this chapter, we discuss the chemical and physical properties of the various classes of lipid molecules. The following chapter considers membranes, whose properties depend intimately on their lipid constituents.

8.1 | What Are the Structures and Chemistry of Fatty Acids?

Fatty acids are lipids that rarely occur as free molecules in nature but are components of more complex lipids. A **fatty acid** is composed of a long hydrocarbon chain (the tail) and a terminal carboxyl group (the head). The carboxyl group is normally ionized under physiological conditions. Fatty acids occur in large amounts in biological systems but only rarely in the free, uncomplexed state. They are typically esterified to glycerol or other backbone structures. Most of the fatty acids found in nature have an even number of carbon atoms (usually 14 to 24). Certain marine organisms, however, contain substantial amounts of fatty acids with odd numbers of carbon atoms. Fatty acids are either **saturated** (all carbon–carbon bonds are single bonds) or **unsaturated**

Table 8.1 Common Biological Fatty Acids

Number of Carbons	Common Name	Systematic Name	Symbol	Structure
Saturated fatty acids				
12	Lauric acid	Dodecanoic acid	12:0	CH ₃ (CH ₂) ₁₀ COOH
14	Myristic acid	Tetradecanoic acid	14:0	CH ₃ (CH ₂) ₁₂ COOH
16	Palmitic acid	Hexadecanoic acid	16:0	CH ₃ (CH ₂) ₁₄ COOH
18	Stearic acid	Octadecanoic acid	18:0	CH ₃ (CH ₂) ₁₆ COOH
20	Arachidic acid	Eicosanoic acid	20:0	CH ₃ (CH ₂) ₁₈ COOH
22	Behenic acid	Docosanoic acid	22:0	CH ₃ (CH ₂) ₂₀ COOH
24	Lignoceric acid	Tetracosanoic acid	24:0	CH ₃ (CH ₂) ₂₂ COOH
Unsaturated fatty acids (all double bonds are cis)				
16	Palmitoleic acid	9-Hexadecenoic acid	16:1*	CH ₃ (CH ₂) ₅ CH=CH(CH ₂) ₇ COOH
18	Oleic acid	9-Octadecenoic acid	18:1	CH ₃ (CH ₂) ₇ CH=CH(CH ₂) ₇ COOH
18	Linoleic acid	9,12-Octadecadienoic acid	18:2	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₂ (CH ₂) ₆ COOH
18	α-Linolenic acid	9,12,15-Octadecatrienoic acid	18:3	CH ₃ CH ₂ (CH=CHCH ₂) ₃ (CH ₂) ₆ COOH
18	γ-Linolenic acid	6,9,12-Octadecatrienoic acid	18:3	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₃ (CH ₂) ₃ COOH
20	Arachidonic acid	5,8,11,14-Eicosatetraenoic acid	20:4	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₄ (CH ₂) ₂ COOH
24	Nervonic acid	15-Tetracosenoic acid	24:1	CH ₃ (CH ₂) ₇ CH=CH(CH ₂) ₁₃ COOH

*Palmitoleic acid can also be described as 16:1^{Δ9}, in a convention used to indicate the position of the double bond.

(with one or more double bonds in the hydrocarbon chain). If a fatty acid has a single double bond, it is said to be **monounsaturated**, and if it has more than one, **polyunsaturated**. Fatty acids can be named or described at least three ways, as shown in Table 8.1. For example, a fatty acid composed of an 18-carbon chain with no double bonds can be called by its systematic name (**octadecanoic acid**), its common name (stearic acid), or its shorthand notation, in which the number of carbons is followed by a colon and the number of double bonds in the molecule (18:0 for stearic acid). The structures of several common fatty acids are given in Figure 8.1. **Stearic acid** (18:0) and **palmitic acid** (16:0) are the most common saturated fatty acids in nature.

Free rotation around each of the C–C single bonds makes saturated fatty acids extremely flexible molecules. Due to steric constraints, however, the fully extended conformation (Figure 8.1) is the most stable for saturated fatty acids. Nonetheless, the degree of stabilization is slight, and (as will be seen) saturated fatty acid chains adopt a variety of conformations.

Unsaturated fatty acids are slightly more abundant in nature than saturated fatty acids, especially in higher plants. The most common unsaturated fatty acid is **oleic acid**, or 18:1^{Δ9}, with the number following the superscript Δ indicating that the double bond is between carbons 9 and 10. The number of double bonds in an unsaturated fatty acid typically varies from one to four, but in the fatty acids found in most bacteria, this number rarely exceeds one.

The double bonds found in fatty acids are nearly always in the *cis* configuration. As shown in Figure 8.1, this causes a bend or *kink* in the fatty acid chain. This bend has very important consequences for the structure of biological membranes. Saturated fatty acid chains can pack closely together to form ordered, rigid arrays under certain conditions, but unsaturated fatty acids prevent such close packing and produce flexible, fluid aggregates.

Some fatty acids are not synthesized by mammals and yet are necessary for normal growth and life. These **essential fatty acids** include **linoleic** and **γ-linolenic acids**. These must be obtained by mammals in their diet (specifically from plant sources). **Arachidonic acid**, which is not found in plants, can be synthesized by mammals only from linoleic acid. At least one function of the essential fatty acids is to serve as a precursor for the

Luis Carlos Jimenez del rio/Shutterstock.com

Olive oil varieties exhibit different fatty acid compositions, with additional variation depending on maturation stage of the fruit and the conditions of growth. For example, Koroneiki olives from Greece contain 12.9% palmitic acid and 74.4% oleic acid, whereas Chemlali olives from Tunisia contain 19.7% palmitic acid and only 54.9% oleic acid.

Figure 8.1 The structures of some typical fatty acids. Note that most natural fatty acids contain an even number of carbon atoms and that the double bonds are nearly always *cis* and rarely conjugated. Fatty acids are shown in their most protonated forms. (a) palmitic acid, (b) stearic acid, (c) oleic acid, (d) linoleic acid, (e) α -linolenic acid, and (f) arachidonic acid.

synthesis of **eicosanoids**, such as prostaglandins, a class of compounds that exert hormone-like effects in many physiological processes.

Fats in the modern human diet vary widely in their fatty acid composition (Table 8.2) but play an important role in human health. The incidence of cardiovascular disease is correlated with diets high in saturated fatty acids. By contrast, a diet relatively higher in unsaturated fatty acids (especially polyunsaturated fatty acids) may reduce the risk of heart attacks and strokes. Although vegetable oils usually contain a higher proportion of unsaturated fatty acids than do animal oils and fats, several plant oils are actually high in saturated fats. Palm oil is low in polyunsaturated fatty acids and particularly high in (saturated) **palmitic acid** (hence the name *palmitic*). Coconut oil is particularly high in lauric and myristic acids (both saturated) and contains little unsaturated fatty acid.

Canola oil has been promoted as a healthy dietary oil because it consists primarily of oleic acid (60%), linoleic acid (20%), and α -linolenic acid (9%) with a very low saturated fat content (7%). Canola oil is actually rapeseed oil, from the seeds of the rape plant *Brassica rapa* (from the Latin *rapa*, meaning “turnip”), a close relative of mustard, kale, cabbage, and broccoli. Asians and Europeans used rapeseed oil in lamps for hundreds of years, but it was not usually considered edible because of its high **erucic**

acid content, a 22:1^{Δ13} monounsaturated fatty acid (often 20% to 60%). In the first half of the twentieth century, it was used as a steam engine lubricant (especially in World War II). Conventional breeding techniques have reduced the erucic acid content to less than 1%, producing the “canola oil” (the name is derived from **Can**adian **oil**, **low acid**) now used so commonly for cooking and baking.

Although most unsaturated fatty acids in nature are *cis* fatty acids, *trans* fatty acids are formed by some bacteria via double-bond migration and isomerization. These bacterial reactions produce *trans* fats in ruminant animals (which carry essential bacteria in their rumen), and butter, milk, cheese, and the meat of these animals contain modest quantities of *trans* fats (typically 2% to 8% by weight), such as those in Figure 8.2. Margarine and other processed fats, made by **partial hydrogenation** of polyunsaturated oils (for example, corn, safflower, and sunflower) contain substantial levels of various *trans* fats, and clinical research has shown that chronic consumption of processed foods containing partially hydrogenated vegetable oils can contribute to cardiovascular disease. Diets high in *trans* fatty acids raise plasma low-density lipoprotein (LDL) cholesterol and triglyceride levels while lowering high-density lipoprotein (HDL) cholesterol levels. The effects of *trans* fatty acids on LDL, HDL, and cholesterol levels are similar to those

Chemistry in History

Alice Ball

Alice Ball (1892–1916) was both the first African American and the first woman to earn a Master of Chemistry from the University of Hawai‘i in 1915. A surgeon at the U.S. Public Health Service in Hawai‘i, learning of her Master’s research on plants, invited Alice to study the oil of the chaulmoogra tree, which had been used for hundreds of years as a treatment for leprosy. Taken by mouth, the oil was an effective remedy, but caused unbearable nausea in patients. Ball learned to convert the fatty acids in the oil to ethyl esters, which were water-soluble and could be injected, without the nauseous side effects. The “Ball Method” was used until the 1940s when it was replaced by synthetic antibiotics. (More modern research showed that the therapeutic fatty acids in chaulmoogra oil contained novel cyclopentenyl rings.)

After finishing her studies, Ball accepted a teaching position at the University of Hawai‘i as a chemistry instructor. Alice died unexpectedly in 1916 at the age of 24 from complications related to chlorine gas inhalation during a lab accident. The president of the college at the time continued her research after her death and claimed the discovery for himself, until a local doctor published a paper on the subject that gave Ball the proper credit she deserved. In 2000, the governor of Hawai‘i declared February 29 “Alice Ball Day”, and a plaque was erected at a chaulmoogra tree on the university campus. Alice Ball was posthumously awarded the Regents Medal of Distinction for her scientific contributions and a scholarship was created in her name.

of saturated fatty acids. Diets aimed at reducing the risk of coronary heart disease should be low in both *trans* and saturated fatty acids. The U.S. Food and Drug Administration (USFDA) has banned trans fats in foods sold in the United States as of May 2019.

8.2 What Are the Structures and Chemistry of Triacylglycerols?

A significant number of the fatty acids in plants and animals exist in the form of *triacylglycerols* (also called **triglycerides**). Triacylglycerols are a major energy reserve and the principal neutral derivatives of glycerol found in animals. These molecules consist of a glycerol esterified with three fatty acids (Figure 8.3). If all three fatty acid groups are the same, the molecule is called a simple triacylglycerol. Examples include *tristearoylglycerol* (common name tristearin) and **trioleoylglycerol** (triolein). Mixed triacylglycerols contain two or three different fatty acids. Triacylglycerols in animals are found primarily in the adipose tissue (body fat), where it serves as a depot or reservoir of stored energy. Monoacylglycerols and diacylglycerols are also found in nature, but they are far less common than the triacylglycerols. Most natural plant and animal fat is composed of mixtures of simple and mixed triacylglycerols.

Acylglycerols can be hydrolyzed by heating with acid or base or by treatment with lipases. Hydrolysis with alkali is called **saponification** and yields salts of free fatty acids and glycerol. This is how our ancestors made *soap* (a metal salt of an acid derived from fat). One method used potassium hydroxide (potash) leached from wood ashes to hydrolyze animal fat (mostly triacylglycerols). (The tendency of such soaps to be precipitated by Mg^{2+} and Ca^{2+} ions in hard water makes them less useful than modern detergents.)

When the fatty acids esterified at the first and third carbons of glycerol are different, the second carbon is asymmetric. The various acylglycerols are normally soluble in benzene, chloroform, ether, and hot ethanol. Although triacylglycerols are insoluble in water, monoacylglycerols and diacylglycerols readily form organized structures in water (see Chapter 9), due to the polarity of their free hydroxyl groups.

Triacylglycerols are rich in highly reduced carbons and thus yield large amounts of energy in the oxidative reactions of metabolism. Complete oxidation of 1 g of triacylglycerols yields about 38 kJ of energy, whereas proteins and carbohydrates yield only about 17 kJ/g. Also, their hydrophobic nature allows them to aggregate in highly

Figure 8.3 Triacylglycerols are formed from glycerol and fatty acids. (a) Glycerol, (b) tristearin, and (c) a mixed triacylglycerol.

A Deeper Look

Polar Bears Prefer Nonpolar Food

The polar bear is magnificently adapted to thrive in its harsh Arctic environment. Research by Malcolm Ramsay at the University of Saskatchewan in Canada and others has shown that polar bears gorge only during a few weeks out of the year and then fast for periods of 8 months or more, consuming no food or water during that time. The adult polar bear feeds almost exclusively on seal blubber (largely composed of triacylglycerols), thus building up its own triacylglycerol reserves. Through the Arctic summer, the polar bear maintains normal physical activity, roaming over long distances, relying almost entirely on its body fat for sustenance, burning as much as 1 kg to 1.5 kg of fat per day. It neither urinates nor defecates for extended periods. All the water needed to sustain life is provided from the metabolism of triacylglycerols because oxidation of fatty acids yields carbon dioxide and water.

Ironically, the word *Arctic* comes from the ancient Greeks, who understood that the northernmost part of the earth lay under the stars of the constellation Ursa Major, the Great Bear. Although unaware of the polar bear, they called this region *Arktikós*, which means “the country of the great bear.”

© Incredible Arctic/Shutterstock.com

anhydrous forms, whereas polysaccharides and proteins are highly hydrated. For these reasons, triacylglycerols are the molecules of choice for energy storage in animals. Body fat (mainly triacylglycerols) also provides good insulation. Whales and Arctic mammals rely on body fat for both insulation and energy reserves.

8.3 What Are the Structures and Chemistry of Glycerophospholipids?

A 1,2-diacylglycerol that has a phosphate group esterified at C-3 of the glycerol backbone is a **glycerophospholipid**, also known as a phosphoglyceride or a glycerol phosphatide (Figure 8.4). These lipids form one of the largest and most important classes of natural lipids. They are essential components of cell membranes and are found in small concentrations in other parts of the cell. It should be noted that all glycerophospholipids are members of the broader class of lipids known as **phospholipids**.

The numbering and nomenclature of glycerophospholipids present a dilemma in that C-2 of the glycerol backbone of a phospholipid is asymmetric. It is possible to name these molecules either as D- or L-isomers. Thus, glycerol phosphate itself can be referred to either as D-glycerol-1-phosphate or as L-glycerol-3-phosphate (Figure 8.5). Instead of naming the glycerol phosphatides in this way, biochemists have adopted the *stereospecific numbering* or *sn*-system. The stereospecific numbering system is based on the concept of prochirality. If a tetrahedral center in a molecule has two identical

Figure 8.4 Phosphatidic acid, the parent compound for glycerophospholipids.

Figure 8.5 (a) The two identical —CH₂OH groups on the central carbon of glycerol may be distinguished by imagining a slight increase in priority for one of them (by replacement of an H by a D) as shown. (b) The absolute configuration of *sn*-glycerol-3-phosphate is shown. The pro-*R* and pro-*S* positions of the parent glycerol are also indicated.

substituents, it is referred to as **prochiral** because if either of the like substituents is converted to a different group, the tetrahedral center then becomes chiral. Consider glycerol (Figure 8.5): The central carbon of glycerol is prochiral because replacing either of the —CH₂OH groups would make the central carbon chiral. Nomenclature for prochiral centers is based on the (*R,S*) system (see Chapter 4). To name the otherwise identical substituents of a prochiral center, imagine increasing slightly the priority of one of them (by substituting a deuterium for a hydrogen, for example) as shown in Figure 8.5. The resulting molecule has an (*S*) configuration about the (now chiral) central carbon atom. The group that contains the deuterium (an isotope of hydrogen with an added neutron) is thus referred to as the pro-*S* group. As a useful exercise, you should confirm that labeling the other CH₂OH group with a deuterium produces the (*R*) configuration at the central carbon so that this latter CH₂OH group is the pro-*R* substituent.

Now consider the two presentations of glycerol phosphate in Figure 8.5. In the stereospecific numbering system, the pro-*S* position of a prochiral atom is denoted as the *1-position*, the prochiral atom as the *2-position*, and so on. When this scheme is used, the prefix *sn*- precedes the molecule name (glycerol phosphate in this case) and distinguishes this nomenclature from other approaches. In this way, the glycerol phosphate in natural phosphoglycerides is named *sn*-glycerol-3-phosphate.

8.3a Glycerophospholipids Are the Most Common Phospholipids

Phosphatidic acid, the parent compound for the glycerol-based phospholipids (Figure 8.4), consists of *sn*-glycerol-3-phosphate, with fatty acids esterified at the 1- and 2-positions. Phosphatidic acid is found in small amounts in most natural systems and is an important intermediate in the biosynthesis of the more common glycerophospholipids (Figure 8.6). In these compounds, a variety of polar groups are esterified to the phosphoric acid moiety of the molecule. The phosphate, together with such esterified entities, is referred to as the head group. Phosphatides with choline or ethanolamine are referred to as **phosphatidylcholine** (known commonly as **lecithin**) or **phosphatidylethanolamine**, respectively. These phosphatides are two of the most common constituents of biological membranes. Other common head groups found in phosphatides include glycerol, serine, and inositol (Figure 8.6). Another kind of glycerol phosphatide found in many tissues is **diphosphatidylglycerol**. First observed in heart tissue, it is also called **cardiolipin**. In cardiolipin, a phosphatidylglycerol is

Figure 8.6 Structures of several glycerophospholipids: (a) Phosphatidylcholine, with shading to indicate the diacylglycerol backbone. (b) Structures built on the same diacylglycerol core: phosphatidylethanolamine, phosphatidylserine, phosphatidylglycerol, diphosphatidylglycerol (cardiolipin) and phosphatidylinositol. (c) Space-filling models of phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol.

esterified through the C-1 hydroxyl group of the glycerol moiety of the head group to the phosphoryl group of another phosphatidic acid molecule.

Phosphatides exist in many different varieties, depending on the fatty acids esterified to the glycerol group. As we shall see, the nature of the fatty acids can greatly affect the chemical and physical properties of the phosphatides and the membranes that contain them. In most cases, glycerol phosphatides have a saturated fatty acid at position 1 and an unsaturated fatty acid at position 2 of the glycerol. Thus, *1-stearoyl-2-oleoyl-phosphatidylcholine* (Figure 8.7) is a common constituent in natural membranes, but *1-linoleoyl-2-palmitoylphosphatidylcholine* is not.

Both structural and functional strategies govern the natural design of the many different kinds of glycerophospholipid head groups and fatty acids. Glycerophospholipids

influence and modulate membrane structure and function. Certain phospholipids, including phosphatidylinositol and phosphatidylcholine, participate in complex cellular signaling events.

8.3b Ether Glycerophospholipids Include PAF and Plasmalogens

Ether glycerophospholipids possess an ether linkage instead of an acyl group at the C-1 position of glycerol (Figure 8.8a). One of the most versatile biochemical signal molecules found in mammals is **platelet-activating factor**, or **PAF**, a unique ether glycerophospholipid (Figure 8.8b). The alkyl group at C-1 of PAF is typically a 16-carbon chain, but the acyl group at C-2 is a 2-carbon acetate group. By virtue of this acetate group, PAF is much more water soluble than other lipids, allowing PAF to function as a soluble messenger in signal transduction.

Plasmalogens are ether glycerophospholipids in which the alkyl moiety is *cis*- α , β -unsaturated (Figure 8.9). Common plasmalogen head groups include choline, ethanolamine, and serine. These lipids are referred to as *phosphatidal choline*, *phosphatidal ethanolamine*, and *phosphatidal serine*.

Human Biochemistry

Platelet-Activating Factor: A Potent Ether Glycerophospholipid Mediator

Platelet-activating factor (PAF) functions in platelet activation and aggregation in the heart, liver, bowel, pancreas, and lungs. It was first identified by its ability to cause platelet aggregation and dilation of blood vessels, but it is now known to be a potent mediator in inflammation, allergic responses, and shock. PAF effects are observed at tissue concentrations as low as 10^{-12} M. PAF causes a dramatic inflammation of air passages and induces asthmatic symptoms in laboratory animals. **Toxic shock syndrome** occurs when fragments of destroyed bacteria act as toxins and induce the

synthesis of PAF. PAF causes a drop in blood pressure and a reduced volume of blood pumped by the heart, which leads to shock and, in severe cases, death.

Beneficial effects have also been attributed to PAF. In reproduction, PAF secreted by the fertilized egg is instrumental in the implantation of the egg in the uterine wall. PAF is produced in significant quantities in the lungs of the fetus late in pregnancy and may stimulate the production of fetal lung surfactant, a protein–lipid complex that prevents collapse of the lungs in a newborn infant.

8.4 | What Are Sphingolipids, and How Are They Important for Higher Animals?

Sphingolipids represent another class of lipids frequently found in biological membranes. An 18-carbon amino alcohol, **sphingosine** (Figure 8.10a), forms the backbone of these lipids rather than glycerol. Typically, a fatty acid is joined to a sphingosine via an amide linkage to form a **ceramide** (Figure 8.10b).

Sphingomyelins represent a phosphorus-containing subclass of sphingolipids and are especially important in the nervous tissue of higher animals. A *sphingomyelin* is formed by the esterification of a phosphorylcholine or a phosphorylethanolamine to the 1-hydroxy group of a ceramide (Figure 8.10c).

Glycosphingolipids are another class of ceramide-based lipids that, like the sphingomyelins, are important components of muscle and nerve membranes in animals. They consist of a ceramide with one or more sugar residues in a β -glycosidic linkage at the 1-hydroxyl moiety. The neutral glycosphingolipids contain only neutral (uncharged) sugar residues. When a single glucose or galactose is bound in this manner, the molecule is a **cerebroside** (Figure 8.10d). (Another class of lipids is formed when a sulfate is esterified at the 3-position of the galactose to make a **sulfatide**.) **Gangliosides** (Figure 8.10e) are more complex glycosphingolipids that consist of a ceramide backbone with three or more sugars esterified, one of these being a **sialic acid** such as *N-acetylneuraminic acid*. These latter compounds are referred to as acidic glycosphingolipids, and they have a net negative charge at neutral pH.

The glycosphingolipids have a number of important cellular functions, despite the fact that they are present only in small amounts in most membranes. Glycosphingolipids at cell surfaces appear to determine, at least in part, certain elements of tissue and organ specificity. Cell–cell recognition and tissue immunity depend on specific glycosphingolipids. Gangliosides are present in nerve endings and are important in nerve impulse transmission. A number of genetically transmitted diseases involve the accumulation of specific glycosphingolipids in the brain due to an absence of the enzymes needed for their degradation. Such is the case for ganglioside G_{M2} in the brains of Tay–Sachs disease victims, a rare but fatal childhood disease characterized by a red spot on the retina, gradual blindness, and self-mutilation.

8.5 | What Are Waxes, and How Are They Used?

Waxes are esters of long-chain alcohols with long-chain fatty acids. The resulting molecule has a weakly polar head group (the ester moiety itself) and a long, nonpolar tail (the hydrocarbon chains) (Figure 8.11). Fatty acids found in waxes are usually saturated. The alcohols found in waxes may be saturated or unsaturated and may include sterols, such as cholesterol (see later section). Waxes are water insoluble due to their mostly hydrocarbon composition. As a result, this class of molecules confers a water-repellant

Figure 8.10 Sphingolipids are based on the structure of sphingosine (a). The amino group (highlighted) is the site of amide linkage with fatty acids to form (b) ceramides (amide linkage highlighted). (c) Addition of a phosphocholine produces a choline sphingomyelin. (d) Addition of a sugar to a ceramide yields a cerebroside. (e) Adding three or more sugars to a ceramide core produces a ganglioside. Typical gangliosides are G_{M1} , G_{M2} and G_{M3} , as indicated.

character to animal skin, to the leaves of certain plants, and to bird feathers. The glossy surface of a polished apple results from a wax coating. *Carnauba wax*, obtained from the fronds of a species of palm tree in Brazil, is a particularly hard wax used for high-gloss finishes, such as in automobile wax, boat wax, floor wax, and shoe polish. **Lanolin**, a wool wax, is used as a base for pharmaceutical and cosmetic products because it is rapidly assimilated by human skin. The brand name Oil of Olay was coined by Graham Wulff, a South African chemist who developed it. The name refers

Novel Lipids with Valuable Properties

Lipids from many natural sources are useful and highly prized materials for many purposes in our world. When oil from the head of the sperm whale is cooled, *spermaceti*, a translucent wax with a white, pearly luster, crystallizes from the mixture. Spermaceti, which makes up 11% of whale oil, is composed mainly of the wax **cetyl palmitate**

as well as smaller amounts of cetyl alcohol:

In the literary classic *Moby Dick*, Herman Melville describes Ishmael's impressions of spermaceti, when he muses that the waxes "discharged all their opulence, like fully ripe grapes their wine; as I snuffed that uncontaminated aroma—literally and truly, like the smell of spring violets."

Spermaceti and cetyl palmitate have been widely used in the making of cosmetics, fragrant soaps, and candles. In addition, the low viscosity of sperm whale oil made it an ideal lubricant for a variety of

industrial applications until whale populations declined precipitously in the twentieth century and commercial whaling was outlawed. Since then, other lipids with similar properties have been sought as replacements for whale oil. One example is the lipids found in the shrub *Euonymus alatus* (also known as the "burning bush"), which makes large amounts of 3-acetyl-1,2-diacyl-*sn*-glycerols (see figure). These unusual glycerols, with two long acyl chains and one short (2-carbon) chain, possess a much lower viscosity than triglycerides with three long chains. As such, they are appropriate for use in biodiesel fuels.

8.6 What Are Terpenes, and What Is Their Relevance to Biological Systems?

The **terpenes** are a class of lipids formed from combinations of two or more molecules of 2-methyl-1,3-butadiene, better known as **isoprene** (a five-carbon unit that is abbreviated C_5). A **monoterpene** (C_{10}) consists of two isoprene units, a **sesquiterpene** (C_{15}) consists of three isoprene units, a **diterpene** (C_{20}) has four isoprene units, and so on. Isoprene units can be linked in terpenes to form straight-chain or cyclic molecules, and the usual method of linking isoprene units is head to tail (Figure 8.12). Monoterpenes occur in all

Figure 8.12 The structure of isoprene (2-methyl-1,3-butadiene) and the structure of head-to-tail and tail-to-tail linkages. Isoprene itself can be formed by distillation of natural rubber, a linear head-to-tail polymer of isoprene units.

higher plants, whereas sesquiterpenes and diterpenes are less widely known. Several examples of these classes of terpenes are shown in Figure 8.13. The *triterpenes* are C_{30} terpenes and include *squalene* and *lanosterol*, two of the precursors of cholesterol and other steroids (discussed later). *Tetraterpenes* (C_{40}) are less common but include the carotenoids, a class of colorful photosynthetic pigments. β -Carotene is the precursor of vitamin A, whereas lycopene, similar to β -carotene, is a pigment found in tomatoes.

Long-chain polyisoprenoid (also known as polyprenyl) molecules with a terminal alcohol moiety are called **polyprenols**. The **dolichols**, one class of polyprenols (Figure 8.14), consist of 16 to 22 isoprene units and, in the form of dolichyl phosphates, function to carry carbohydrate units in the biosynthesis of glycoproteins in animals. Polyprenyl groups serve to anchor certain proteins to biological membranes.

Figure 8.13 Structures of common terpenes. Highlighting in two cases shows the isoprene building blocks of the molecule. (a) Many monoterpenes are readily recognized by their characteristic flavors or odors (limonene in lemons; citronellal in roses, geraniums, and some perfumes; and menthol from peppermint, used in cough drops and nasal inhalers). (b) Bisabolene and eudesmol are sesquiterpenes. (c) The diterpenes, which are C_{20} terpenes, include retinal (the essential light-absorbing pigment in rhodopsin, the photoreceptor protein of the eye), and phytol (a constituent of chlorophyll). (d) The triterpene lanosterol is a constituent of wool fat. (e) Lycopene is a carotenoid found in ripe fruit, especially tomatoes.

Figure 8.14 Dolichol phosphate is an initiation point for the synthesis of carbohydrate polymers in animals. The analogous alcohol in bacterial systems, *undecaprenol*, also known as *bactoprenol*, consists of 11 isoprene units. Undecaprenyl phosphate delivers sugars from the cytoplasm for the synthesis of cell wall components such as peptidoglycans, lipopolysaccharides, and glycoproteins.

Why Do Plants Emit Isoprene?

The Blue Ridge Mountains of Virginia are so named for the misty blue vapor or haze that hangs over them through much of the summer season. This haze is composed in part of isoprene that is produced and emitted by the plants and trees of the mountains. Global emission of isoprene from vegetation is estimated at 3×10^{14} g/yr. Plants frequently emit as much as 15% of the carbon fixed in photosynthesis as isoprene, and Thomas Sharkey, a botanist at the University of Wisconsin, has shown that the kudzu plant can emit as much as 67% of its fixed carbon as isoprene as the result of water stress. Why should plants and trees emit large amounts of isoprene and other hydrocarbons? Sharkey has shown that an isoprene atmosphere or “blanket” can protect leaves from irreversible damage induced by high (summerlike) temperatures. He hypothesizes that isoprene in the air around plants dissolves into leaf-cell membranes, altering the lipid bilayer and/or lipid–protein and protein–protein interactions within the membrane to increase thermal tolerance.

Human Biochemistry

Coumadin or Warfarin—Agent of Life or Death

The isoprene-derived molecule whose structure is shown here is known alternately as **Coumadin** and **warfarin**. Warfarin (as it was first named) was promoted as a rodent poison. Later, it was marketed and prescribed as the anticoagulant coumadin, a tradename that distinguished it from its original usage. How can the same chemical species be used for such disparate purposes? The key to both uses lies in its ability to act as an antagonist of vitamin K in the body.

Vitamin K is necessary for the carboxylation of glutamate residues on certain proteins, including some proteins in the blood-clotting cascade (including *prothrombin*, *factor VII*, *factor IX*, and *factor X*, which undergo a Ca^{2+} -dependent conformational change in the course of their biological activity as well as *protein C* and *protein S*, two regulatory proteins in coagulation). Carboxylation of these coagulation factors is catalyzed by a carboxylase that requires the reduced form of vitamin K (vitamin KH_2), molecular oxygen, and carbon dioxide. Oxidation and recycling of vitamin K is shown in the figure. KH_2 is oxidized to vitamin K epoxide, which is recycled to KH_2 by the enzymes (1) **vitamin K epoxide reductase** and (2,3) **vitamin K reductase**. Coumadin/warfarin exerts its anticoagulant effect by inhibiting vitamin K epoxide reductase and possibly also vitamin K reductase. This inhibition depletes vitamin KH_2 and reduces the activity of the carboxylase.

Coumadin/warfarin, given at a typical dosage of 4 mg/day to 5 mg/day, prevents the deleterious formation in the bloodstream of small blood clots and thus reduces the risk of heart attacks and strokes for individuals whose arteries contain sclerotic plaques. Taken in much larger doses, as for example in rodent poisons, Coumadin/warfarin can cause massive hemorrhages and death.

Figure 8.15 The structure of caldarchaeol, an isoprene-based lipid found in Archaea. Glycerol groups are highlighted.

The Membranes of Archaea Are Rich in Isoprene-Based Lipids Archaea are ubiquitous, but they were first discovered in harsh environments. Some thrive in the high temperatures of geysers and ocean steam vents, whereas others are found in extremely acidic, cold, or salty environments. Archaea also live in extremes of pH in the digestive tracts of cows, termites, and humans. Many archaea are well adapted to harsh environments, and one such adaptation is found in their cell membranes, which contain isoprene-based lipids (Figure 8.15). These isoprene chains are linked at both ends by ether bonds to glycerols. Ether bonds are more stable to hydrolysis than the ester linkages of glycerophospholipids (Figure 8.6). With a length twice that of typical glycerophospholipids, these molecules can completely span a cell membrane, providing additional stability. Interestingly, the glycerols in archaeal lipids are in the (*R*) configuration, whereas glycerolipids of animals, plants, and eubacteria are almost always in the (*S*) configuration.

8.7 What Are Steroids, and What Are Their Cellular Functions?

A large and important class of terpene-based lipids is the **steroids**. This molecular family, whose members affect an amazing array of cellular functions, is based on a common structural motif of three 6-membered rings and one 5-membered ring all fused together.

8.7a Cholesterol

Cholesterol (Figure 8.16) is the most common steroid in animals and the precursor for all other animal steroids. The numbering system for cholesterol applies to all such molecules. Many steroids contain methyl groups at positions 10 and 13 and an 8- to 10-carbon alkyl side chain at position 17. The polyprenyl nature of this compound is particularly evident in the side chain. Many steroids contain an oxygen at C-3, either a hydroxyl group in sterols or a carbonyl group in other steroids. The carbons at positions 10 and 13 and the alkyl group at position 17 are nearly always oriented on the same side of the steroid nucleus, the β -orientation. Alkyl groups that extend from the other side of the steroid backbone are in an α -orientation.

Cholesterol is a principal component of animal cell plasma membranes, and smaller amounts of cholesterol are found in the membranes of intracellular organelles. The relatively rigid fused ring system of cholesterol and the weakly polar alcohol group at the C-3 position have important consequences for the properties of plasma membranes. Cholesterol is also a component of lipoprotein complexes in the blood, and it is one of the constituents of plaques that form on arterial walls in atherosclerosis.

8.7b Steroid Hormones Are Derived from Cholesterol

Steroids derived from cholesterol in animals include five families of hormones (the androgens, estrogens, progestins, glucocorticoids, and mineralocorticoids) and bile acids (Figure 8.17). **Androgens** such as **testosterone** and **estrogens** such as **estradiol**

Figure 8.16 The structure of cholesterol, shown with steroid ring designations and carbon numbering. When cholesterol is viewed as shown here, the β -orientation is above the page. A space-filling model of cholesterol is shown at right.

Figure 8.17 The structures of several important sterols derived from cholesterol.

mediate the development of sexual characteristics and sexual function in animals. The **progestins** such as **progesterone** participate in control of the menstrual cycle and pregnancy. **Glucocorticoids** (**cortisol**, for example) participate in the control of carbohydrate, protein, and lipid metabolism, whereas the **mineralocorticoids** regulate salt (Na^+ , K^+ , and Cl^-) balances in tissues. The **bile acids** (including **cholic** and **deoxycholic acid**) are detergent molecules secreted in bile from the gallbladder that assist in the absorption of dietary lipids in the intestine.

Human Biochemistry

Plant Sterols and Stanols—Natural Cholesterol Fighters

Dietary guidelines for optimal health call for reducing the cholesterol intake. Plant sterols and stanols are a healthier substitute for cholesterol. Despite their structural similarity to cholesterol, minor isomeric differences and the presence of methyl and ethyl groups in the side chains of these substances result in their poor absorption by intestinal mucosal cells. Interestingly, stanols are even less well absorbed than their sterol counterparts. (Stanols are fully reduced sterols that is, with no double bonds). Both

sterols and stanols bind to cholesterol receptors on intestinal cells and block the absorption of cholesterol itself. Stanols esterified with long-chain fatty acids form micelles that are more effectively distributed in the fat phase of digested food and provide the most effective blockage of cholesterol uptake. Raisio Group, a Finnish company, has developed Benecol, a stanol ester spread that can lower LDL cholesterol by up to 14% if consumed daily (see graph).

Serum cholesterol levels before and after the consumption of margarine with and without sitostanol ester for 12 months. Green circles: 0 g/day. Red squares: 2.6 g/day. Blue triangles: 1.8 g/day. Note: The y-axis begins at 200 mg cholesterol/dL. (Adapted from Miettinen, T. A., et al., 1995. *Reduction of serum cholesterol with sitostanol-ester margarine in a mildly hypercholesterolemic population*. New England Journal of Medicine **333**:1308–1312.)

8.8 How Do Lipid Metabolites Act as Biological Signals?

Glycerophospholipids and sphingolipids play important structural roles as the principal components of biological membranes. However, their modification and breakdown also produce an eclectic assortment of substances that act as powerful **chemical signals** (Figures 8.18 and 8.19). In contrast to the steroid hormones (Figure 8.17), which travel from tissue to tissue in the blood to exert their effects, these lipid metabolites act

Human Biochemistry

Beating COVID-19: Lipid Nanoparticles Make RNA Vaccines Practical and Effective

RNA-based vaccines for protection against infectious diseases like the coronavirus that causes COVID-19 depend on novel ionizable lipid nanoparticles (LNPs). Messenger RNA is sensitive and easily degraded by enzymes in the environment and in human tissue. LNPs package the messenger RNA of these vaccines and protect it on its perilous journey from hypodermic needle to human lymph node cells. The four critical components of the LNPs are shown in the figure: A special *ionizable lipid*, cholesterol, a glycerophospholipid (distearoylphosphatidylcholine - DSPC), and a diacylglycerol linked to polyethyleneglycol (PEG). The PEG controls particle size and improves stability of the particles. The cholesterol and glycerophospholipid are termed helper lipids and form the impermeable outer membrane of the LNP.

The ionizable lipid has a pK_a near 6.5 and is uncharged upon injection of the vaccine. When the LNPs encounter lymph node cells, they are taken up in endosomes, whose pH decreases to about 4.5, protonating the ionizable lipid. The acquired positive charge enables the lipid to encapsulate the negatively-charged RNA molecules and facilitates interaction with the endosome membrane to release the RNA into the cytosol, initiating the desired immune response.

The Pfizer-BioNTech and Moderna vaccines consist of lipid nanoparticles like the one at upper right. The ionizable lipids of the Pfizer-BioNTech (ALC-0315) and Moderna (SM-102) vaccines are shown. The highlighted nitrogens have pK_a values of about 6.5. Uptake by endosomes protonates at the N to produce the ionized form of the molecule.

locally, either within the cell in which they are made or on nearby cells. Signal molecules typically initiate a cascade of reactions with multiple possible effects, and the lifetimes of these signals in or near a cell are usually very short. Thus, the creation and breakdown of signal molecules is almost always carefully timed and regulated.

Enzymes known as **phospholipases** hydrolyze the ester bonds of glycerophospholipids, as shown in Figure 8.18. Phospholipases A_1 and A_2 remove fatty acid chains from the 1- and 2-positions of glycerophospholipids, respectively. Phospholipases C and D attack the polar head group of a glycerophospholipid. Hydrolysis of inositol phospholipids by phospholipase C produces a **diacylglycerol** and **inositol-1,4,5-trisphosphate (IP_3)** (Figure 8.19), two signal molecules whose combined actions

Figure 8.18 Phospholipases are enzymes that cleave and degrade glycerophospholipids. Phospholipases are components of the venoms of many poisonous snakes. The pain and physiological consequences of a snake bite result partly from breakdown of cell membranes by phospholipases. (a) Phospholipases A₁ and A₂ cleave fatty acids from a glycerophospholipid, producing lysophospholipids. Phospholipases C and D hydrolyze on either side of the phosphate in the polar head group. (b) Diamondback rattlesnake. (c) Indian cobra.

Figure 8.19 Modification and breakdown of glycerophospholipids produce a variety of signals and regulatory effects. (a) Phospholipase A₂ cleaves a fatty acid from phosphatidic acid to produce lysophosphatidic acid (LPA), which can act as an extracellular signal. If the fatty acid released is arachidonic acid, it can be the substrate for synthesis of prostaglandins, thromboxanes, and leukotrienes. (b) Phospholipase C action on phosphatidylinositol-4,5-bisphosphate produces diacylglycerol and inositol-1,4,5-trisphosphate, two signal molecules that work together to activate protein kinases—enzymes that phosphorylate other proteins in signaling pathways.

Human Biochemistry

The Endocannabinoid Signaling System: A Target for Next-Generation Therapeutics

Chemical signals called neurotransmitters are the fundamental mode of intercellular communication in the nervous system. The classic neurotransmitters are small, soluble molecules derived from amino acids (or are amino acids themselves). However, recent research has shown that lipids known as **endocannabinoids** are chemical messengers that operate by a novel mechanism. This class of chemical

signals came to light originally from studies of the physiological effects of Δ^9 -tetrahydrocannabinol and other metabolites from *Cannabis sativa*, better known as marijuana. Early research showed that the effects of *Cannabis* involved binding of its metabolites to specific receptor proteins in the brain. Further research demonstrated that these receptors are normally activated by endogenous lipid

(Continued)

molecules. Two of these are *anandamide* and *2-arachidonoylglycerol* (2AG). The biosyntheses of these signal molecules are shown in the figure. Biosynthesis of anandamide from N-arachidonoylphosphatidylethanolamine (NAPE) appears to proceed by at least three different routes in neurons.

Endocannabinoids are termed **retrograde** messengers because they traverse the synaptic cleft in the opposite direction of classical neurotransmitters. Activated endocannabinoid receptors can act to either inhibit or activate neuronal circuits, depending on the type of neurons involved. Research on the physical and functional relationships between endocannabinoid receptors and the proteins with which they interact reveals novel targets for drug discovery.

Human Biochemistry

Fingolimod—a Sphingosine-1-P Mimic Is an Oral Drug for Multiple Sclerosis

Multiple sclerosis (MS) is a chronic disabling autoimmune disorder. In MS, the body's natural defense system mistakenly attacks myelin, the lipid-rich sheath that protects the nerves. About 400,000 U.S. citizens have multiple sclerosis. Earlier treatments for MS were all injectable medications, until **fingolimod** was approved by the USFDA for relapsing forms of multiple sclerosis. It was the first oral disease-modifying therapy to be approved for multiple sclerosis in the United States.

In multiple sclerosis, lymph nodes release certain types of lymphocytes (themselves a type of white blood cell), which migrate to and invade the central nervous system, killing neural cells. Lymphocyte release from the lymph nodes is induced by binding of sphingosine-1-phosphate (S1P) to receptors on the lymphocyte surface. Fingolimod, an analog of sphingosine, is phosphorylated by sphingosine kinase enzymes, forming (*S*)-fingolimod-phosphate (F1P). Binding of F1P to lymphocyte S1P receptors prevents these lymphocytes from migrating to target tissues, averting further lymphocyte-induced neural cell destruction.

trigger signaling cascades that regulate many cell processes. Action of phospholipase A_2 on a phosphatidic acid releases a fatty acid and a *lysophosphatidic acid* (LPA, Figure 8.19). If the fatty acid is arachidonic acid, further chemical modifications can produce a family of 20-carbon compounds—that is, **eicosanoids**. The eicosanoids are local hormones produced as a response to injury and inflammation. They exert their effects on cells near their sites of synthesis. LPA produced outside the cell is a signal that can bind to receptor proteins on nearby cells, thereby regulating a host of processes, including brain development, cell proliferation and survival, and olfaction (the sense of smell).

The venoms of poisonous snakes contain (among other things) a class of enzymes known as **phospholipases**, enzymes that cause the breakdown of phospholipids. For example, the venoms of the eastern diamondback rattlesnake (*Crotalus adamanteus*) and the Indian cobra (*Naja naja*) both contain phospholipase A_2 , which catalyzes the hydrolysis of fatty acids at the C-2 position of glycerophospholipids (Figure 8.18). The phospholipid breakdown product of this reaction, *lysolecithin*, acts as a detergent and dissolves the membranes of red blood cells, causing them to rupture. Indian cobras kill several thousand people each year.

Sphingolipids can also be modified or broken down to produce chemical signals. Sphingosine itself can be phosphorylated to produce **sphingosine-1-phosphate (S1P)** inside cells (Figure 8.20). S1P may either exert a variety of intracellular effects or may be secreted from the cell, to bind membrane receptor proteins, either on adjacent cells or on the cell from which the S1P was released. Secreted S1P binds to at least five different receptor proteins and provokes many different cell and tissue effects, among them inflammation in allergic reactions, cell proliferation, angiogenesis, malignant transformation, movement, and migration of certain cells. Sphingolipid signal molecules are carefully balanced and regulated in organisms, and chemical agents that disturb this balance can be highly toxic. For example, *fumonisin* is a common fungal contaminant of corn and corn-based products that inhibits sphingolipid biosynthesis (Figure 8.20). Fumonisin can trigger esophageal cancer in humans and *leucoencephalomalacia*, a fatal neurological disease in horses.

Figure 8.20 Signaling by sphingosine-1-phosphate (S1P). (a) Sphingosine is derived from ceramides and is phosphorylated to give sphingosine-1-phosphate (S1P). (b) After transport out of the cell, S1P can bind to at least five different receptor proteins. Activation of each of these receptors elicits different intracellular responses. Fingolimod-1-phosphate (see Human Biochemistry box in this section) binds to and activates the same receptors, with the exception of S1P2.

8.9 What Can Lipidomics Tell Us about Cell, Tissue, and Organ Physiology?

The crucial role of lipids in cells is demonstrated by the large number of human diseases that involve the disruption of lipid metabolic enzymes and pathways. Examples of such diseases include atherosclerosis, diabetes, cancer, infectious diseases, and neurodegenerative diseases. A new approach - **lipidomics** - allows scientists to perform global analyses of lipids and their interacting protein partners in organs, cells, and organelles. A typical cell may contain more than a thousand different lipids, each with a polar head and a hydrophobic tail or tails. The LIPID MAPS Structure Database (LMSD) at <http://www.lipidmaps.org/data/structureindex.html>, annotates more than 40,000 biologically relevant lipids. There is an increasing awareness of the critical importance of lipids in all aspects of life.

Interestingly, lipid compositions vary in many ways:

- Between species
- Between individuals within a given species
- Within an individual from day to day

- Between tissues within an organism
- Between cell types
- Between cellular compartments
- Between regions of a cellular compartment
- Between parts of a membrane

Complete understanding of lipid function, as well as alteration of such function in disease states, will require the determination of which lipids are present and in what concentrations in every intracellular location. The same knowledge will be needed about each lipid's interaction partners. Mass spectrometric analyses of rat heart muscle lipids reveal that the onset of diabetes results in dramatic changes in triglyceride levels, an increase in phosphatidylinositol levels, and a decrease in phosphatidylethanolamine. On the other hand, mass spectrometric analyses of brain white matter lipids in the very early stages of Alzheimer's disease show a dramatic decrease in one type of plasmalogen and a threefold increase in ceramide levels. Three-dimensional mass spectral imaging can provide three-dimensional maps of individual lipid species in biological tissues and organs (Figure 8.21).

Cellular lipidomics provides a framework for understanding the myriad roles of lipids, which include (but are not limited to) membrane transport, metabolic regulation, and cell signaling. For example, six different classes of lipids have been shown to modulate systems important in the regulation of pain responses. Each of these classes of lipids exerts its action by interacting with one or more receptor proteins. True understanding of the molecular basis for diseases and physiologic conditions may require comprehensive and simultaneous analyses of many lipid species and their respective receptors.

Figure 8.21 Identification and three-dimensional mapping of lipids in the crab (*Cancer borealis*) brain. **(a)** Representative mass spectrometry (MS) spectrum of lipids from crab brain slice with the masses and identities of each peak labeled; **(b)** Comparison of three-dimensional distribution of two different species of lipids PC 36:1 (upper) and SM 16:0 (lower). (Adapted from Chen, R., Hui, L., Sturm, R. M., and Li, L., 2009. Three dimensional mapping of neuropeptides and lipids in crustacean brain by mass spectral imaging. *J. Amer. Soc. Mass Spectrom.* **20**:1068–1077.)

Foundational Biochemistry Things You Should Know after Reading Chapter 8.

- Lipids found in biological systems are either hydrophobic (containing only non-polar groups) or amphipathic (possessing both polar and nonpolar groups).
- Fatty acids are composed of a long hydrocarbon chain (the tail) and a terminal carboxyl group (the head).
- Fatty acids may be saturated (all C-C bonds are single bonds) or unsaturated (with one or more double bonds in the hydrocarbon chain).
- The double bonds of nearly all fatty acids in nature are *cis* double bonds.
- Triacylglycerols (also called triglycerides) consist of a glycerol esterified with three fatty acids.
- Triacylglycerols are a major energy reserve and the principal neutral derivatives of glycerol found in animals.
- A glycerophospholipid is a 1,2-diacylglycerol that has a phosphate group esterified at carbon C-3 of the glycerol backbone.
- Glycerol is a prochiral molecule and, according to the stereospecific numbering convention, the pro-*S* carbon of glycerol is designated as C-1.
- A variety of polar groups may be esterified to the phosphate of a glycerophospholipid, including choline, ethanolamine, glycerol, serine, inositol, and even another phosphatide (in diphosphatidylglycerol, also known as cardiolipin).
- Platelet activating factor (PAF) and the plasmalogens are ether glycerophospholipids.
- Sphingolipids are based on the 18-carbon alcohol, sphingosine. A fatty acid in amide linkage to sphingosine yields a ceramide, and a ceramide with one or more sugars in β -glycosidic linkage at the 1-hydroxyl moiety of sphingosine is a glycosphingolipid.
- Common sphingolipids include sphingomyelins, cerebroside, and gangliosides.
- Terpenes are formed from combinations of two or more molecules of 2-methyl-1,3-butadiene, also known as isoprene. Terpene-based lipids include monoterpenes, sesquiterpenes, diterpenes, and triterpenes (including squalene, lanosterol, and cholesterol).
- Steroids are based on a common structural motif of three 6-membered rings and one 5-membered ring.
- Cholesterol is a principal component of animal cell plasma membranes. Cholesterol is the precursor of the androgens (such as testosterone), estrogens (such as estradiol), and the glucocorticoids (for example, cortisol), the mineralocorticoids, and the bile acids.
- The action of phospholipases produces derivatives of glycerophospholipids and sphingolipids that can act as biological signals.
- Lipidomics is the global analysis of lipids and their interacting protein partners in organs, cell, and organelles.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Drawing Structures of Triacylglycerols** Draw the structures of (a) all the possible triacylglycerols that can be formed from glycerol with stearic and arachidonic acid and (b) all the phosphatidylserine isomers that can be formed from palmitic and linolenic acids.
- Distinguishing Structures of Glycerolipids, Steroids, and Sphingolipids** Describe in your own words the structural features of
 - a ceramide and how it differs from a cerebroside.
 - a phosphatidylethanolamine and how it differs from a phosphatidylcholine.
 - an ether glycerophospholipid and how it differs from a plasmalogen.
 - a ganglioside and how it differs from a cerebroside.
 - testosterone and how it differs from estradiol.
- Identifying Glycerophospholipids** From your memory of the structures, name the glycerophospholipids that
 - carry a net positive charge at pH 7.
 - carry a net negative charge at pH 7.
 - have zero net charge at pH 7.
- Properties of Phospholipids** Glycerophospholipids (shown in Figure 8.6.) are the major components of cell membranes. Just like phosphates (PO_4), sulfates (SO_4) can make diester forms of molecules. Imagine a class of molecules known as glycerosulfolipids: An imaginary class of lipids in which the phosphate group of the glycerophospholipids is replaced with a sulfate group. Discuss a critical difference that would exist between the glycerophospholipids and the imaginary glycerosulfolipids.
- Comparing Health Effects of Cholesterol and Plant Sterols** Compare and contrast two individuals, one whose diet consists largely of meats containing high levels of cholesterol and the other whose diet is rich in plant sterols. Are their risks of cardiovascular disease likely to be similar or different? Explain your reasoning.
- Evaluating Organic Secretions of Trees** James G. Watt, Secretary of the Interior (1981–1983) in Ronald Reagan's first term, provoked substantial controversy by stating publicly that trees cause significant amounts of air pollution. Based on your reading of this chapter, evaluate Watt's remarks.
- Evaluating Nutritional Benefits of Foods** In a departure from his usual and highly popular westerns, author Louis L'Amour wrote a novel in 1987, *Last of the Breed* (Bantam Press), in which a military pilot with Indigenous heritage is shot down over the former Soviet Union and is forced to use the survival skills of his ancestral culture to escape his enemies. On the rare occasions when he is able to trap and kill an animal for food, he selectively eats the fat, not the meat. Based on your reading of this chapter, what is his reasoning for doing so?
- Exploring the Action of Phospholipase A_2** As you read Section 8.7, you might have noticed that phospholipase A_2 , the enzyme found in rattlesnake venom, is also the enzyme that produces essential and beneficial lipid signals in most organisms. Explain the differing actions of phospholipase A_2 in these processes.
- Evaluating the Action of Warfarin** Pet owners often worry about unintended ingestion of rodent poisons. Visit a grocery store near you, stop by the rodent poison section, and examine a container of warfarin or a related product. From what you can glean from the packaging, how much warfarin would a typical dog (40 lbs) have to consume to risk hemorrhages and/or death?
- Understanding Isoprene Structures** Refer to Figure 8.13 and draw each of the structures shown and try to identify the isoprene units in each of the molecules. (Note that there may be more than one correct answer for some of these molecules.)
- Evaluating the Caloric Content of Stored Fat** (Integrates with Chapter 3.) As noted in the Deeper Look box on polar bears, a polar bear may burn as much as 1.5 kg of fat resources per day. What weight of seal

blubber would you have to ingest if you were to obtain all your calories from this energy source?

12. **Omega-3 Fatty Acids** Omega-3 (or ω -3) fatty acids are a class of polyunsaturated fatty acids that have a double bond at the third carbon counting from the last (omega) carbon of the fatty acid chain. Identify the omega-3 fatty acid or acids in Table 8.1.
13. **Assessing the Fat Composition of Desserts** If you are still at the grocery store working on problem 9, stop by the cookie shelves and choose your three favorite cookies from the shelves. Estimate how many calories of fat and how many other calories from other sources are contained in 100 g of each of these cookies. Survey the ingredients listed on each package, and describe the contents of the package in terms of (a) saturated fat, (b) cholesterol, and (c) *trans* fatty acids. (Note that food makers are required to list ingredients in order of decreasing amounts in each package.)
14. **Evaluating the Structures of Sterols** Describe all of the structural differences between cholesterol and stigmasterol.
15. **Understanding the Functions of Steroid Hormones** Describe the functions of androgens, glucocorticoids, and mineralocorticoids.
16. **Understanding Structures and Properties of Terpenes** Look through your refrigerator, your medicine cabinet, and your cleaning solutions shelf or cabinet, and find at least three commercial products that contain fragrant monoterpenes. Identify each one by its scent and then draw its structure.
17. **Terpenes in Lipid Structures** Lanosterol (see Figure 8.13d) is an important precursor in the biosynthesis of cholesterol. Identify the isoprene units (see Figure 8.12) in lanosterol. How many are present?
18. **Understanding the Chemistry of Soaps** Our ancestors kept clean with homemade soap (see Section 8.2), often called lye soap. Go to <http://www.wikihow.com/Make-Your-Own-Soap> and read the procedure for making lye soap from vegetable oils and lye (sodium hydroxide). What chemical process occurs in the making of lye soap? Draw reactions to explain. How does this soap work as a cleaner?
19. **Understanding the Chemistry of Common Foods** Mayonnaise is mostly vegetable oil and vinegar. So what's the essential difference between oil and vinegar salad dressing and mayonnaise? Learn for yourself: Combine a half cup of pure vegetable oil (olive oil will work) with two tablespoons of vinegar in a bottle, cap it securely, and shake the mixture vigorously. What do you see? Now let the mixture sit undisturbed for an hour. What do you see now? Add one egg yolk to the mixture, and shake vigorously again. Let the mixture stand as before. What do you see after an hour? After two hours? Egg yolk is rich in phosphatidylcholine. Explain why the egg yolk caused the effect you observed.
20. **Ether or Ester Linkages in Lipids** Ether glycerophospholipids contain an ether bond between glycerol and an acyl chain. From a chemical or biochemical point of view, what is the benefit of having an ether bond rather than an ester bond between the glycerol and acyl chains?
21. **Evaluating the Physiological Benefits of Stanol Esters** The cholesterol-lowering benefit of stanol-ester margarine is only achieved after months of consumption of stanol esters (see graph in the Human Biochemistry box "Plant Sterols and Stanols—Natural Cholesterol Fighters" in Section 8.7). Suggest why this might be so. Suppose dietary sources represent approximately 25% of total serum cholesterol. Based on the data in the graph, how effective are stanol esters at preventing uptake of dietary cholesterol?
22. **Comparing Therapies for Cholesterol Lowering** Statins are cholesterol-lowering drugs that block cholesterol synthesis in the human liver (see the Human Biochemistry box "Statins Lower Serum Cholesterol" in

Section 24.4). Would you expect the beneficial effects of stanol esters and statins to be duplicative or additive? Explain.

23. **Assessing the Sterol and Stanol Content of Food Products** If most plant-derived food products contain plant sterols and stanols, would it be as effective for cholesterol-lowering purposes to simply incorporate plant fats in one's diet as to use a sterol- or stanol-fortified spread like Benecol? Consult a suitable reference (for example, <http://lpi.oregonstate.edu/info/center/phytochemicals/sterols/#sources> at the Linus Pauling Institute) to compose your answer.
24. **Evaluating the History and Culture of Anabolic Steroids** Tetrahydrogestrinone is an anabolic steroid. It was banned by the USFDA in 2003, but it has been used illegally since then by athletes to increase muscle mass and strength. Nicknamed "The Clear," it has received considerable attention in high-profile steroid-abuse cases among athletes such as baseball player Barry Bonds and track star Marion Jones. Use your favorite web search engine to learn more about this illicit drug. How is it synthesized? Who is the father of prohormones who first synthesized it? Why did so many prominent athletes use The Clear (and its relative "The Cream") when less expensive and more commonly available anabolic steroids are in common use? (Hint: There are at least two answers to this last question.)

Tetrahydrogestrinone

25. Make a list of the advantages polar bears enjoy from their nonpolar diet. Why wouldn't juvenile polar bears thrive on an exclusively nonpolar diet?
26. Snake venom phospholipase A₂ causes death by generating membrane-soluble anionic fragments from glycerophospholipids. Predict the fatal effects of such molecules on membrane proteins and lipids.
27. Testosterone, the principal male sex steroid hormone, is synthesized in five steps from cholesterol. In the last step, five isozymes catalyze the 17 β -hydroxysteroid dehydrogenase reaction that interconverts 4-androstenedione and testosterone. Defects in the synthesis or action of testosterone can impair the development of the male phenotype during embryogenesis and cause the disorders of human sexuality termed male pseudohermaphroditism. Consult a suitable reference (for example, Anderson, S., Russell, D. W., and Wilson, J. D., 1996. 17 β -Hydroxysteroid dehydrogenase 3 deficiency. *Trends in Endocrinology and Metabolism* 7:121–126; or Yang, S.-Y., He, X.-Y., and Miller, D., 2011. Hydroxysteroid (17 β) dehydrogenase X in human health and disease. *Mol. Cell Endocrinol.* 343:1–6) to learn more about the consequences of alterations of steroid biosynthesis. How are these alterations involved in Alzheimer's disease and Down's syndrome?
28. Phosphatidylinositol is sometimes mistakenly taken to be a glycerophospholipid—specifically a phosphatidyl glycoside. However, the head group of phosphatidylinositol is a poly-hydroxy cyclohexane, not a monosaccharide. On the other hand, a true glycerophospholipid, namely phosphatidyl- β -D-glucopyranoside (or simply phosphatidylglucoside), has been identified in several cell types, including HL-60 cells (a line of human leukemia cells used frequently for studies of blood cell formation). In these cells, phosphatidylglucoside plays a role in the formation of plasma membrane signaling microdomains involved in cellular differentiation and maturation. Consult a suitable reference (for example, Greimel, P., and Ito, Y., 2008. First synthesis of natural phosphatidyl- β -D-glucoside. *Tetrahedron Letters* 49:3562–3566.) to learn more about its role in glial cell development and differentiation.

29. A signaling pathway begins with a particular membrane glycerophospholipid and produces several signal molecules by enzymatic reactions.
- The first enzyme reaction cleaves this beginning glycerophospholipid to produce a phosphatidic acid and a phosphatidylglycerol. Name the enzyme that carried out this reaction.
 - Reaction of the phosphatidylglycerol with an enzyme produces glycerol and another molecule of phosphatidic acid. Name the enzyme that carried out this reaction.
 - The phosphatidic acids produced in the two reactions described above turned out to be identical. They were treated with another enzyme to yield arachidonic acid and a second molecule. Name the enzyme that carried out this reaction.
 - Name the second molecule produced in this third reaction.
30. 2- α -linolenoylglycerol-3-phosphate may be produced by a series of two reactions from a phosphatidylcholine that contains linoleic acid. The first reaction removes a fatty acid from the PC. Draw and name the structures of the starting phospholipid and all the products produced in these two reactions. Name both enzymes.
31. Acknowledging the threat to human health of *trans* fats, the USFDA has banned the addition of partially hydrogenated oils (PHOs) in all foods produced and sold in the U.S. However, there are natural sources of *trans* fats in various foods, particularly milk, cheese, and meats from ruminant animals. What are the sources of these *trans* fats in these foods? What are the levels of *trans* fats in these foods? The USFDA actually

allows food manufacturers to label their products as having “Zero grams *trans* fat per serving”, even when these foods contain *trans* fats. How is this possible? Consult the USFDA guidelines to learn more and explain this apparent inconsistency.

Think-Pair-Share question

32. **ATP Content from Fatty Acids in Food Items** In a fatty acid, every pair of carbons ($-\text{CH}_2-\text{CH}_2-$) can generate about 13.5 molecules of ATP when it is broken down in metabolism. However, if the pair of carbons from an unsaturated bond ($-\text{CH}=\text{CH}-$), then about 12 molecules of ATP can be generated.

Consider the nutritional information of the two energy bars.

	Energy bar 1	Energy bar 2
Serving size (g)	68	52
% (w/w) saturated fat	1.25	1.12
% (w/w) monounsaturated fat	0.524	1.5
% (w/w) polyunsaturated fat	2.35	2.8

Using stearic acid ($\text{C}_{18}\text{H}_{36}\text{O}_2$), oleic acid ($\text{C}_{18}\text{H}_{34}\text{O}_2$) and α -linolenic acid ($\text{C}_{18}\text{H}_{30}\text{O}_2$) as your models for saturated, monounsaturated, and polyunsaturated fatty acids (see Table 8.1), calculate the number of moles of ATP that can be generated from these energy bars.

Membranes and Membrane Transport

9

It takes a membrane to make sense out of disorder in biology.

Lewis Thomas
The World's Biggest Membrane,
The Lives of a Cell (1974)

iStockphoto.com/Tree4Two

◀ Frog eggs are macroscopic facsimiles of microscopic cells. All cells are surrounded by a thin, delicate yet stable membrane.

Essential Question

Membranes serve a number of essential cellular functions. They constitute the boundaries of cells and intracellular organelles, and they provide a surface where many important biological reactions and processes occur. Membranes have proteins that mediate and regulate the transport of metabolites, macromolecules, and ions. Photosynthesis, electron transport, oxidative phosphorylation, muscle contraction, and electrical activity all depend on membranes. **What are the properties and characteristics of biological membranes that account for their broad influence on cellular processes and transport?**

Membranes are key structural and functional elements of cells. All cells have a cytoplasmic membrane, or *plasma membrane*, that functions (in part) to separate the cytoplasm from the surroundings. The plasma membrane is also responsible for (1) the exclusion of certain toxic ions and molecules from the cell, (2) the accumulation of cell nutrients, and (3) energy transduction. It also functions in (4) cell locomotion, (5) reproduction, (6) signal transduction processes, and (7) interactions with molecules or other cells in the vicinity. Hormones and many other biological signal molecules and regulatory agents exert their effects via interactions with membranes and membrane proteins. As an index of the importance of membranes, an estimated 26% of human protein-coding genes encode membrane proteins.

Even the plasma membranes of prokaryotic cells are complex (Figure 9.1). With no intracellular organelles to divide and organize the work, bacteria carry out processes either at the plasma membrane or in the cytoplasm itself. Eukaryotic cells, however, contain numerous intracellular organelles that perform specialized tasks. Nucleic acid biosynthesis is handled in the nucleus; mitochondria are the site of electron transport, oxidative phosphorylation, fatty acid oxidation, and the tricarboxylic acid cycle; and the secretion of proteins and other substances is handled by the endoplasmic reticulum

Key Questions

- 9.1 What Are the Chemical and Physical Properties of Membranes?
- 9.2 What Are the Structure and Chemistry of Membrane Proteins?
- 9.3 How Are Biological Membranes Organized?
- 9.4 What Are the Dynamic Processes That Modulate Membrane Function?
- 9.5 How Does Transport Occur across Biological Membranes?
- 9.6 What Is Passive Diffusion?
- 9.7 How Does Facilitated Diffusion Occur?
- 9.8 How Does Energy Input Drive Active Transport Processes?
- 9.9 How Are Certain Transport Processes Driven by Light Energy?
- 9.10 How Is Secondary Active Transport Driven by Ion Gradients?

Figure 9.1 Electron micrographs of several different membrane structures: **(a)** Plasma membrane of *Menoidium*, a protozoan. **(b)** Two plasma membranes from adjacent neurons in the central nervous system. **(c)** Golgi apparatus. **(d)** Many membrane structures are evident in pancreatic acinar cells.

(ER) and the Golgi apparatus. This partitioning of labor is not the only contribution of the membranes in these cells. Many of the processes occurring in these organelles (or in the prokaryotic cell) actively involve membranes. Thus, some of the enzymes involved in nucleic acid metabolism are membrane associated. The electron transfer chain and its associated system for ATP synthesis are embedded in the mitochondrial membrane. Many enzymes responsible for aspects of lipid biosynthesis are located in the ER membrane. This chapter discusses the composition, structure, and dynamic processes of biological membranes.

9.1 What Are the Chemical and Physical Properties of Membranes?

The interactions of lipids and proteins to form membranes are based on several properties of water. These include water's tendency to form hydrogen bonds, share in polar interactions, and the hydrophobic effect, which promotes self-association of lipids in water to maximize entropy. These forces drive amphiphilic glycerolipids, sphingolipids, and sterols to form membrane structures in water, and they facilitate the association of proteins (and thus myriad biological functions) with membranes. A symphony of molecular events over a range of times from picoseconds to many seconds results in the movement of lipids and proteins across and between membranes; coordinates reactions at or in the membrane and the transport of ions, sugars, and amino acids across membranes; and organizes and directs hundreds of cell-signaling events.

9.1a The Composition of Membranes Suits Their Functions

Biological membranes may contain as much as 75% to 80% protein (and only 20% to 25% lipid) or as little as 15% to 20% protein. Membranes that carry out many enzyme-catalyzed reactions and transport activities (the inner mitochondrial membrane, chloroplast membranes, and the plasma membrane of *Escherichia coli*, for example) are typically richer in protein, whereas membranes that carry out fewer protein-related functions (myelin sheaths, the protective coating around neurons, for example) are richer in lipid.

Figure 9.2 The lipid composition of rat liver cell membranes, in weight percent. (Adapted from Andreoli, T. E., 1987. *Membrane Physiology*, 2nd ed. Chapter 27, Table II, and Daum, G., 1985. Lipids of mitochondria. *Biochimica et Biophysica Acta* 822:1–42.)

Cellular mechanisms adjust lipid composition to functional needs. Thus, for example, the lipid makeup of red blood cell membranes is consistent across species, whereas the lipid complement of different (specialized) membranes within a particular cell type (rat liver, Figure 9.2) reflects differences of function. Plasma membranes are enriched in cholesterol but do not contain diphosphatidylglycerol (cardiolipin), whereas mitochondria contain considerable amounts of cardiolipin (essential for some mitochondrial proteins) and no cholesterol. The protein components of membranes vary even more greatly than their lipid compositions.

9.1b Lipids Form Ordered Structures Spontaneously in Water

Amphipathic lipids spontaneously form a variety of structures when added to aqueous solution. All these structures form in ways that minimize contact between the hydrophobic lipid chains and the aqueous milieu.

Monolayers and Micelles When small amounts of a fatty acid are added to an aqueous solution, a monolayer is formed at the air–water interface, with the polar head groups in contact with the water surface and the hydrophobic tails in contact with the air (Figure 9.3). Few lipid molecules are found as monomers in solution.

Careers in Chemistry

Dr. Audie Thompson

Encouraged by her mother to study science, Dr. Audie Key Thompson received a B.S. in Biology from Alcorn State University, an M.S. in Biology from Alabama State University, and a Ph.D. in Biochemistry from the University of Mississippi Medical Center. Her dissertation research involved the role of copper chaperones in the assembly of cytochrome c oxidase in *Rhodobacter sphaeroides*. A year of postdoctoral research at Prairie View A&M University sparked her interest in membrane technology and bio-separations.

Dr. Thompson is presently an Assistant Professor of Chemical Engineering at the University of Arkansas, where she is developing enzymatic methods for removal of bacterial toxins from public water supplies. Professor Thompson has served as Chair of the Minority Affairs Committee of the American Institute of Chemical Engineers. She works to encourage engagement of undergraduate students in research and the training of underrepresented groups for leadership roles in science and society.

Figure 9.3 Several spontaneously formed lipid structures. Drawings of (a) monolayers and bilayers, (b) micelles, (c) a unilamellar vesicle, (d) a multilamellar vesicle, and (e) an electron micrograph of a multilamellar Golgi structure.

Further addition of fatty acid eventually results in the formation of micelles. **Micelles** formed from an amphipathic lipid in water position the hydrophobic tails in the center of the lipid aggregation with the polar head groups facing outward. Amphipathic molecules that form micelles are characterized by a unique **critical micelle concentration**, or **CMC**. Below the CMC, individual lipid molecules predominate. Nearly all the lipid added above the CMC, however, spontaneously forms micelles. Micelles are the preferred form of aggregation in water for detergents and soaps. Some typical CMC values are listed in Figure 9.4.

Lipid Bilayers The fundamental structure of membranes is the **lipid bilayer**, which consists of back-to-back arrangements of monolayers (Figure 9.3). The nonpolar portions of the lipids face the middle of the bilayer, with the polar head groups arrayed on the bilayer surface. Phospholipid bilayers form rapidly and spontaneously when phospholipids are added to water, and they are stable structures in aqueous solution. As opposed to micelles, which are small, self-limiting structures of a few hundred molecules, bilayers may form spontaneously over large areas (10^8 nm^2 or more). Because exposure of the edges of the bilayer to solvent is highly unfavorable, extensive bilayers normally wrap around themselves and form closed vesicles (Figure 9.3). The nature and integrity of these vesicle structures are very much dependent on the lipid composition. Physicochemical studies in the laboratory with these substances reveal that phospholipids can form either *unilamellar vesicles* (with a single lipid bilayer), known as *liposomes*, or *multilamellar vesicles*. These latter structures are reminiscent of the layered structure of onions.

Liposomes are highly stable structures, a consequence of the amphipathic nature of the phospholipid molecule. Ionic interactions between the polar head groups and water are maximized, whereas hydrophobic interactions (see Chapter 2) facilitate the association

Structure	M _r	CMC	Micelle M _r
Triton X-100 	625	0.24 mM	90–95,000
Octyl glucoside 	292	25 mM	
C₁₂E₈ (Dodecyl octaoxyethylene ether) $\text{C}_{12}\text{H}_{25} - (\text{OCH}_2\text{CH}_2)_8 - \text{OH}$	538	0.071 mM	

Figure 9.4 The structures of some common detergents and their physical properties. Micelles formed by detergents can be quite large. Triton X-100, for example, typically forms micelles with a total molecular mass of 90 kDa to 95 kDa. This corresponds to approximately 150 molecules of Triton X-100 per micelle.

of hydrocarbon chains in the interior of the bilayer. The formation of vesicles results in a favorable increase in the entropy of the solution because the water molecules are not required to order themselves around the lipid chains. It is important to consider for a moment the physical properties of the bilayer membrane, which is the basis of vesicles and also of natural membranes. Bilayers have a polar surface and a nonpolar core. This hydrophobic core provides a substantial barrier to ions and other polar entities. The rates of movement of such species across membranes are thus quite slow. However, this same core also provides a favorable environment for nonpolar molecules and hydrophobic proteins. We will encounter numerous cases of hydrophobic molecules that interact with membranes and regulate biological functions in some way by binding to or embedding themselves in membranes.

9.1c The Fluid Mosaic Model Describes Membrane Dynamics

In 1972, S. J. Singer and G. L. Nicolson proposed the **fluid mosaic model** for membrane structure, which suggested that membranes are dynamic structures composed of proteins and phospholipids. In this model, the phospholipid bilayer is a *fluid matrix*, in essence, a two-dimensional solvent for proteins. Both lipids and proteins are capable of rotational and lateral movement.

Singer and Nicolson also pointed out that a mosaic of proteins can be associated with the surface of this bilayer or embedded in the bilayer to varying degrees (Figure 9.5). They defined two classes of membrane proteins. The first, called **peripheral proteins** (or **extrinsic proteins**), includes those that do not penetrate the bilayer to any significant degree and are associated with the membrane by virtue of ionic interactions and hydrogen bonds between the membrane surface and the surface of the protein. Peripheral proteins can be dissociated from the membrane by treatment with salt solutions or by changes in pH (treatments that disrupt hydrogen bonds and ionic interactions). **Integral proteins** (or **intrinsic proteins**), in contrast, possess hydrophobic surfaces that can readily penetrate the lipid bilayer itself, as well as surfaces that prefer contact with the aqueous medium. These proteins can either insert themselves into the membrane or extend all the way across the membrane and expose themselves to the aqueous solvent on both sides. Singer and Nicolson also suggested that a portion of the bilayer lipid interacts in specific ways with integral membrane proteins and that these interactions might be important for the function of certain membrane proteins. Because of these intimate associations with membrane lipid, integral proteins can be removed from the membrane only by agents

Figure 9.5 The fluid mosaic model of membrane structure proposed by S. J. Singer and G. L. Nicolson. In this model, the lipids and proteins are assumed to be mobile; they can diffuse laterally in the plane of the membrane. Transverse motion may also occur, but it is much slower.

such as detergents or organic solvents that are capable of breaking up the hydrophobic interactions within the lipid bilayer itself. The fluid mosaic model became the paradigm for modern studies that have advanced our understanding of membrane structure and function.

The Thickness of a Membrane Depends on Its Components Electron micrographs of typical cellular membranes show the thickness of the entire membrane—including lipid bilayer and embedded protein—to be 50 Å or more. Electron microscopy, NMR, and X-ray and neutron diffraction measurements have shown that membrane thickness is influenced by the particular lipids and proteins in the membrane. The thickness of a phospholipid bilayer made from dipalmitoyl phosphatidylcholine, measured as the phosphorus-to-phosphorus spacing, is about 37 Å, and the hydrophobic phase of such membranes is approximately 26 Å thick. Natural membranes are thicker overall than simple lipid bilayers because many membrane proteins extend out of the bilayer significantly.

Among the known membrane protein structures, there is considerable variation in the hydrophobic surface perpendicular to the membrane plane. If the hydrophobic surface of the protein is larger or smaller than the lipid bilayer, the thickness of the lipid bilayer must be increased or decreased. The change in bilayer thickness due to membrane proteins can be as much as 5 Å.

Lipid Chains May Bend and Tilt in the Membrane The long hydrocarbon chains of lipids are typically portrayed as more or less perpendicular to the membrane plane (Figure 9.3). In fact, the hydrocarbon tails of phospholipids may tilt and bend and adopt a variety of orientations. Typically, the portions of a lipid chain near the membrane surface lie most nearly perpendicular to the membrane plane, and lipid chain ordering decreases toward the end of the chain (toward the middle of the bilayer).

Membranes Are Crowded with Many Different Proteins Membranes are crowded places, with a large number of proteins either embedded or associated in some way. The *E. coli* genome codes for more than a thousand membrane proteins. Moreover, as more membrane protein structures are determined (Figure 9.6), it has become apparent that many membrane proteins have large structures extending outside the lipid bilayer that share steric contacts and other interactions.

Figure 9.6 Membrane protein structures solved since the first structure in 1985. As of March, 2022, more than 1400 structures had been published. (Data from the Web site Membrane Proteins of Known 3D Structure at the laboratory of Stephen H. White, <http://blanco.biomol.uci.edu/mpstruc>. See also: <http://webclu.bio.wzw.tum.de/binfol/proj/proamp>.)

9.2 What Are the Structure and Chemistry of Membrane Proteins?

Although the lipid bilayer constitutes the fundamental structural unit of all biological membranes, proteins carry out essentially all of the active functions of membranes. Singer and Nicolson defined two classes of membrane proteins. Peripheral proteins are globular proteins that interact with the membrane mainly through electrostatic and hydrogen-bonding interactions, and integral proteins are those that are strongly associated with the lipid bilayer. Another class of proteins not anticipated by Singer and Nicolson, the **lipid-anchored proteins**, is important in a variety of functions in different cells and tissues. These proteins associate with membranes by means of a variety of covalently linked lipid anchors.

9.2a Peripheral Membrane Proteins Associate Loosely with the Membrane

Peripheral proteins can bind to membranes in several ways (Figure 9.7). They may form ionic interactions and hydrogen bonds with polar head groups of membrane lipids or with other (integral) proteins, or they may interact with the nonpolar membrane core by inserting a hydrophobic loop or an amphipathic α -helix. Examples of each of these interaction types are shown in Figure 9.8.

9.2b Integral Membrane Proteins Are Firmly Anchored in the Membrane

Hundreds of structures of integral membrane proteins are now available in the Protein Data Bank, and the number of membrane protein structures is doubling about every 3 years. The known structures show a surprising diversity, but in all cases the

Figure 9.7 Four possible modes for the binding of peripheral membrane proteins.

portions of the protein in contact with the nonpolar core of the lipid bilayer are dominated by α -helices or β -sheets because these secondary structures neutralize the highly polar N—H and C=O functions of the peptide backbone through H-bond formation. There are three classes of integral proteins. **Monotopic** proteins are associated with only one face of the membrane. **Bitopic** proteins span the bilayer once, whereas **polytopic** proteins span the bilayer multiple times (Figure 9.9).

Bitopic Proteins Possess a Single Transmembrane Segment In proteins that are anchored by a single hydrophobic segment, that segment typically takes the form of an α -helix. One of the best examples is **glycophorin**. Most of glycophorin's mass is oriented on the outside surface of the red blood cell, exposed to the aqueous milieu (Figure 9.10). Hydrophilic oligosaccharide units are attached to this extracellular domain. These oligosaccharide groups constitute the ABO and MNS blood group antigenic specificities of the red cell. Glycophorin has a total molecular weight of about 31,000 and is approximately 40% protein and 60% carbohydrate. The glycophorin primary structure consists of a segment of 19 hydrophobic amino acid residues with a short hydrophilic sequence on one end and a longer hydrophilic sequence on the other end. The 19-residue sequence is just the right length to span the cell membrane if it is coiled in the shape of an α -helix.

Monoamine oxidase from the mitochondrial outer membrane is another typical single transmembrane-segment protein (Figure 9.11); this enzyme is the target for many antidepressant and neuroprotective drugs. Each monomer of the dimeric protein binds to the membrane through a C-terminal transmembrane α -helix. Residues in two loops (Pro-109 and Ile-110 in the 99–112 loop and Phe-481, Leu-482, Leu-486, and Pro-487 in the 481–488 loop) also provide nonpolar residues that participate in membrane binding.

Figure 9.8 Models for membrane association of peripheral proteins. (a) Bee venom phospholipase A₂ (PDB id = 1POC), (b) p40 phox PX domain of NADH oxidase (PDB id = 1H6H), and (c) PH domain of phospholipase C δ (PDB id = 1MAI). Amphipathic α -helices dominate the membrane interaction in (a) and (b), whereas hydrophobic loops are shown in (c).

Figure 9.9 Three classes of membrane proteins. (a) Integral membrane proteins are classified as monotopic, bitopic, or polytopic, depending on the topology of their membrane association. (b) PglC is a phosphoglycosyltransferase from *Campylobacter concisus* and is an integral monotopic protein. PglC associates with the membrane via three α -helices at the membrane surface and one α -helix imbedded in the membrane. The bend in the latter helix occurs at a proline residue (PDB id = 5W7L). (Adapted from Figure 1 of Ray, L. C., et al., 2018. Membrane association of monotopic phosphoglycosyl transferase underlies function. *Nature Chemical Biology* 14: 538–541.)

Figure 9.10 Glycophorin A spans the membrane of the human erythrocyte via a single α -helical transmembrane segment. The C-terminus of the peptide faces the cytosol of the erythrocyte; the N-terminal domain is extracellular. Points of attachment of oligosaccharide groups are indicated by triangles.

The number of TM segments found in membrane proteins varies between 1 and 33, with most proteins predicted to have between 1 and 12 TM regions. The largest group of membrane proteins has only one predicted TM segment. In animals, many of these function as cell surface receptors for extracellular signaling molecules or as recognition sites that allow the immune system to recognize and distinguish cells of the host organism from invading foreign cells or viruses. The proteins that represent the *major transplantation antigens H2* in mice (Figure 9.11) and *human leukocyte antigen (HLA) proteins* in humans are members of this class. Other such proteins include the *surface immunoglobulin receptors* on B lymphocytes and the *spike proteins* of many membrane viruses. The function of many of these proteins depends primarily on their extracellular domain; thus, the segment facing the intracellular surface is often a shorter one.

Polytopic Proteins Have Multiple Transmembrane Segments Many integral transmembrane proteins cross the lipid bilayer more than once. These **multi-spanning** membrane proteins typically have 2 to 12 transmembrane segments, and they carry out a variety of cellular functions (Figure 9.12). A well-characterized example of such a protein is **bacteriorhodopsin** (Figure 9.13), which clusters in purple patches in the membrane of the archaeon *Halobacterium halobium*. The name *Halobacterium* refers to the fact that this prokaryote thrives in solutions with high concentrations of sodium chloride, such as the salt ponds of San Francisco Bay. *H. halobium* carries out a light-driven proton transport by means of bacteriorhodopsin, named in reference to its spectral similarities to rhodopsin in the rod outer segments of the mammalian retina. The amino acid sequence of bacteriorhodopsin contains seven different segments, each about 20 non-polar residues in length—just the right size for an α -helix that could span a bilayer membrane. (Twenty residues times 1.5 Å per residue equals 30 Å.)

Figure 9.11 Partial structures of proteins with a single transmembrane segment. (Complete structures are not available.) **(a)** Major histocompatibility antigen HLA-A2 (PDB id = 1JF1). The arrow notes the presumed connection with the transmembrane segment. **(b)** Monoamine oxidase (PDB id = 1GOS). Both are membrane-associated proteins with a single transmembrane helical segment.

Figure 9.13 Bacteriorhodopsin is composed of seven transmembrane α -helical segments connected by short loops (PDB id = 1M0M). Nearly all of this protein is embedded in the membrane. Only the short loops connecting helices are exposed to solvent. A retinal chromophore (a light-absorbing molecule, shown in *blue*) lies approximately parallel to the membrane and between the helical segments. A proline residue (*red*) induces a kink in one of the helical segments (*green*).

Figure 9.12 The vast majority of membrane proteins possess 1 to 12 transmembrane segments, though a few percent of known proteins have more. Those involved in transport functions have between 6 and 12 transmembrane segments. (Adapted from von Heijne, G., 2006. Membrane-protein topology. *Nature Reviews Molecular Cell Biology* 7:909–918.)

Bacteriorhodopsin clusters in symmetric, repeating arrays in the purple membrane patches of *H. halobium*, and it was this orderly, repeating arrangement of proteins in the membrane that enabled Nigel Unwin and Richard Henderson in 1975 to determine the bacteriorhodopsin structure. The polypeptide chain crosses the membrane seven times, in seven α -helical segments, with very little of the protein exposed to the aqueous milieu. The bacteriorhodopsin structure became a model of globular membrane protein structure. Many other integral membrane proteins contain numerous hydrophobic sequences that, like those of bacteriorhodopsin, form α -helical transmembrane segments.

Table 9.1 Hydropathy Scale for Amino Acid Side Chains in Proteins*	
Side Chain	Hydropathy Index
Isoleucine	4.5
Valine	4.2
Leucine	3.8
Phenylalanine	2.8
Cysteine	2.5
Methionine	1.9
Alanine	1.8
Glycine	−0.4
Threonine	−0.7
Serine	−0.8
Tryptophan	−0.9
Tyrosine	−1.3
Proline	−1.6
Histidine	−3.2
Glutamic acid	−3.5
Glutamine	−3.5
Aspartic acid	−3.5
Asparagine	−3.5
Lysine	−3.9
Arginine	−4.5

*From Kyte, J., and Doolittle, R., 1982. A simple method for displaying the hydropathic character of a protein. *Journal of Molecular Biology* 157:105–132.

Membrane Protein Topology Can Be Revealed by Hydropathy Plots The **topology** of a membrane protein is a specification of the number of transmembrane segments and their orientation across the membrane. The topology of a transmembrane helical protein can be revealed by a **hydropathy plot** based on its amino acid sequence. If a measure of hydrophobicity is assigned to each amino acid (Table 9.1), then the overall hydrophobicity of a segment of a polypeptide chain can be estimated. The **hydropathy index** for any segment is an average of the hydrophobicity values for its residues.

The hydropathy index can be calculated at any residue in a sequence by averaging the hydrophobicity values for a segment surrounding that residue. Typically, segment sizes for such calculations can be 7 to 21 residues. With a 7-residue segment size, the calculation of hydropathy index at residue 10 would average the values for residues 7 through 13. The calculation for a 21-residue segment around residue 100 would include residues 90 to 110. A polypeptide segment approximately 20 residues long with a high hydropathy index is likely to be an α -helical transmembrane segment. A hydropathy plot for glycophorin (Figure 9.14a) reveals a single region of high hydropathy index between residues 73 and 93, the location of the α -helical segment in this transmembrane protein (see Figure 9.10). A hydropathy plot for rhodopsin (Figure 9.14b) reveals the locations of its seven α -helical transmembrane segments. Rhodopsin, the light-absorbing pigment protein of the eye, is a member of the *G-protein-coupled receptor (GPCR)* family of membrane proteins.

Proline Residues Can Bend a Transmembrane α -Helix Transmembrane α -helices often contain distortions and kinks—more so than for water-soluble proteins. As more integral membrane protein structures have been determined, it has become clear that most transmembrane α -helices contain significant distortions from ideal helix geometry. Helix distortions may have evolved in membrane proteins because (1) helices, even distorted ones, are highly stable in the membrane environment, and (2) helix distortions may be one way to create structural diversity.

About 60% of known membrane helix distortions are kinks at proline residues (see Figure 9.13). Proline distorts the ideal α -helical geometry because of its fixed ϕ

Figure 9.14 Hydropathy plots for (a) glycophorin and (b) rhodopsin. Hydropathy index is plotted versus residue number. At each position in the polypeptide chain, the average of hydropathy indices for a certain number of adjacent residues (eight, in this case) is calculated and plotted on the y-index, and the number of the residue in the middle of this window is shown on the x-axis.

value, steric conflict with the preceding residue, and because of the loss of a backbone H bond. Proline-induced kinks create weak points in the helix, which may facilitate movements required for transmembrane transport channels.

Amino Acids Have Preferred Locations in Transmembrane Helices Transmembrane protein sequences and structures are adapted to the transition from water on one side of the membrane, to the hydrocarbon core of the membrane, and then to water on the other side of the membrane. The amino acids that make up transmembrane segments reflect these transitions. Charged residues (Figure 9.15a) occur commonly at the lipid–water interface, but positively charged residues are found more often on the cytoplasmic face of transmembrane proteins. Hydrophobic amino acids (Ala, Val, Leu, Ile, and Phe) are found most often in the hydrocarbon interior, where charged and polar amino acids almost never reside (Figure 9.15b). Gunnar von Heijne has termed this the **positive inside rule**. Tryptophan, histidine, and tyrosine are special cases (Figure 9.15c). These residues have a mixed character, with nonpolar

Figure 9.15 Amino acids have distinct preferences for different parts of the membrane. The graphs show relative stabilization energies as a function of location in the membrane for (a) Arg, Asp, Glu, Lys, Asn, Gln, and Pro; (b) Ala, Gly, Ile, Leu, Met, Phe, and Val; and (c) His, Tyr, and Trp. In general, polar and charged residues are less stable in the membrane interior, whereas nonpolar residues tend to be more stable in the membrane interior. The stability profiles for His, Tyr, and Trp are more complex. (Adapted from von Heijne, G., 2006. Membrane-protein topology. *Nature Reviews Molecular and Cell Biology* 7:909–918.)

Figure 9.16 Snorkeling and ant snorkeling behavior in membrane proteins. The SdhC subunit of succinate dehydrogenase (PDB id = 1NEK). Lys¹¹¹ snorkels away from the membrane core and Phe⁷² ant snorkels toward the membrane core. Numbers at left indicate lipid bilayer dimensions in angstroms. (Adapted from Liang, J., Adamian, L., and Jackups, R., Jr., 2005. The membrane–water interface region of membrane proteins: Structural bias and the anti-snorkeling effect. *Trends in Biochemical Sciences* 30:355–357.)

aromatic rings that also contain polar parts (the ring N—H of Trp and the substituent —OH of Tyr). As such, Trp and Tyr are found commonly at the lipid–water interface of transmembrane proteins.

The amino acids Lys and Arg frequently behave in novel ways at the lipid–water interface. Both of these residues possess long aliphatic side chains with positively charged groups at the end. In many membrane proteins, the aliphatic chain of Lys or Arg is associated with the hydrophobic portion of the bilayer, with the positively charged groups (amino or guanidinium) extending beyond to associate with negatively charged phosphate groups. This behavior, with the side chain pointing up out of the membrane core, has been termed *snorkeling* (Figure 9.16). If a Phe residue occurs near the lipid–water interface, it is typically arranged with the aromatic ring oriented toward the membrane core. This is termed *ant snorkeling*.

Membrane Protein Structures Show Many Variations on the Classical Themes Although it revealed many insights of membrane protein structure, bacteriorhodopsin gave a relatively limited view of the structural landscape. Many membrane protein structures obtained since bacteriorhodopsin (and a few others) have provided a vastly more complex picture to biochemists. For example, the structures of a homodimeric chloride ion transport protein and a glutamate transport protein show several novel structural features (Figure 9.17). In addition to several transmembrane helices that lie perpendicular to the membrane plane (like those of bacteriorhodopsin), these structures each contain several *long, severely tilted helices* that span the membrane. Both these proteins also contain several **reentrant loops**, consisting of a pair of short α -helices and a connecting loop that together penetrate partway into the membrane core. There are also regions of **nonhelical polypeptide** deep in the membrane core of these proteins, with helical segments on either side that extend to the membrane surface (Figure 9.17). Some transmembrane helices are hydrophobic throughout their length, and these tilt largely to avoid exposing nonpolar residues to the water solvent. Other transmembrane helices have a mix of polar and nonpolar residues at one or both ends of the helix. In these cases, the helix tilt is the result of specific interactions of these polar residues with other parts of the protein. Nonpolar residues in these capping segments face the surrounding membrane.

Finally, most membrane protein structures are relatively stable; that is, transmembrane helices do not flip in and out of the membrane, and they do not flip across the lipid bilayer, inverting their orientation. However, a few membrane proteins can in fact change their membrane orientation. Aquaporin-1 is a protein that functions normally

Figure 9.17 Not all the embedded segments of membrane proteins are transmembrane and oriented perpendicular to the membrane plane. (a) The glutamate transporter homolog (PDB id = 1XFH). Reentrant helices (orange) and interrupted helices (red) are shown. Several of the transmembrane helices deviate significantly from the perpendicular. (b) The *E. coli* CIC chloride transporter (PDB id = 1KPK). Few of the transmembrane helices are perpendicular to the membrane plane.

Figure 9.18 Dynamic insertion of helical segments of membrane proteins. **(a)** Aquaporin-1. The second and fourth transmembrane helices insert properly across the membrane only after reorientation of the third transmembrane helix. **(b)** The large envelope glycoprotein of the hepatitis B virus. The N-terminal pre-S domain translocates across the endoplasmic reticulum membrane in a slow process in 50% of the molecules. (Adapted from von Heijne, G., 2006. *Nature Reviews Molecular and Cell Biology* 7:909–918.)

with six transmembrane α -helices. When this protein is first inserted into its membrane, it has only four transmembrane α -helices (Figure 9.18a). One of these, the third transmembrane helix (TM3), reorients across the membrane, pulling helices two and four into the membrane. Similarly, a glycoprotein of the hepatitis B virus is initially inserted into the viral membrane with its N-terminal domain lying outside. During the viral maturation process, about half of these glycoproteins rearrange (Figure 9.18b), with the N-terminal segment moving across the membrane as TM4 creates a new transmembrane segment.

Some Proteins Use β -Strands and β -Barrels to Span the Membrane The α -helix is not the only structural motif by which a protein can cross a membrane. Some integral transmembrane proteins use structures built from β -strands and β -sheets to diminish the polar character of the peptide backbone as it crosses the nonpolar membrane core. These **β -barrel** structures (Figure 9.19) maximize hydrogen bonding and are highly stable. The barrel interior is large enough to accommodate water molecules and often structures as large as peptide chains, and most barrels are literally water filled.

How does the β -barrel structure tolerate water on one surface (the inside) and the nonpolar membrane core on the other? In all transmembrane β -barrels, polar and nonpolar residues alternate along the β -strands, with polar residues facing the center of the barrel and nonpolar residues facing outward, where they can interact with the hydrophobic lipid milieu of the membrane.

Porin proteins found in the outer membranes (OMs) of gram-negative bacteria such as *E. coli*, and also in the outer mitochondrial membranes of eukaryotic cells, span their respective membranes with large β -barrels. A good example is *maltoporin*, also known as *LamB protein* or *lambda receptor*, which participates in the entry of maltose and maltodextrins into *E. coli*. Maltoporin is active as a trimer. The 421-residue monomer

Figure 9.19 Some proteins traverse the membrane with β -barrel structures. Several examples are shown, including (a) maltoporin from *Salmonella typhimurium* (PDB id = 2MPR), (b) ferric enterobactin receptor (PDB id = 1FEP), (c) TolC, an outer membrane protein from *E. coli* (PDB id = 1EK9), (d) the translocator domain of the NalP autotransporter of *N. meningitidis* (PDB id = 1UYN), (e) the translocator domain of the Hia autotransporter from *Haemophilus influenzae* (PDB id = 2GR8), (f) the outer membrane cobalamin transporter from *E. coli*, in a complex with the 100 Å coiled coil of colicin E3 (PDB id = 1UJW), (g) the fatty acid transporter FadL from *E. coli* (PDB id = 1T16).

Figure 9.20 The arrangement of the peptide chain in maltoporin from *E. coli*. Porins are located in the outer membranes of gram-negative bacteria and in the outer membranes of mitochondria. The periplasmic space is the region between inner and outer membranes.

forms an 18-strand β -barrel with antiparallel β -strands connected to their nearest neighbors either by long loops or by β -turns (Figure 9.20; see also Figure 9.19a). The long loops are found at the end of the barrel that is exposed to the cell exterior, whereas the turns are located on the intracellular face of the barrel. Three of the loops fold into the center of the barrel.

β -barrels can also be constructed from multiple subunits. The α -hemolysin toxin (Figure 9.21) forms a 14-stranded β -barrel with seven identical subunits that each contribute two antiparallel β -strands connected by a short loop. *Staphylococcus aureus* secretes monomers of this toxin, which bind to the plasma membranes of host blood cells. Upon binding, the monomers oligomerize to form the seven-subunit structure. The channel thus formed facilitates uncontrolled permeation of water, ions, and small molecules, destroying the host cell.

Why have certain proteins evolved to use β -strands instead of α -helices as membrane-crossing devices? Among other reasons, there is an advantage of genetic

Figure 9.21 The structure of the heptameric channel formed by *Staphylococcus aureus* α -hemolysin. Each of the seven subunits contributes a β -sheet hairpin to the transmembrane channel (PDB id = 7AHL).

economy in the use of β -strands to traverse the membrane instead of α -helices. An α -helix requires 21 to 25 amino acid residues to span a typical biological membrane; a β -strand can cross the same membrane with 9 to 11 residues. Therefore, a given amount of genetic information could encode a larger number of membrane-spanning segments using a β -strand motif instead of α -helical arrays.

Transmembrane Barrels Can Also Be Formed with α -Helices Many bacteria, including *E. coli*, produce extracellular polysaccharides, some of which form a discrete structural layer—the **capsule**, which shields the cell, allowing it to evade or counteract host immune systems. In *E. coli*, the components of this polysaccharide capsule are synthesized inside the cell and then transported outward through an octameric outer membrane protein called *Wza*. To cross the outer membrane, *Wza* uses a distinctive **α -helical barrel** (Figure 9.22). *Wza* is composed of three novel domains that, with the α -helical barrel, form a large central cavity that accommodates the transported

Figure 9.22 The structure of *Wza*, an octameric membrane protein that anchors the peptidoglycan layer and the outer membrane of gram-negative bacteria. The structure contains a central barrel (black lines) constructed from α -helical segments (PDB id = 2J58). Axial view is from bottom of the structure in the side view.

Prenyl groups are linked to target proteins by the actions of farnesyl and geranylgeranyl transferases, which play crucial roles in multiple cell-signaling pathways and are thus promising therapeutic targets for a variety of cancers and other diseases.

polysaccharides. The transmembrane α -helices of Wza are amphiphilic, with hydrophobic outer surfaces that face the lipid bilayer and hydrophilic inner surfaces that face the water-filled pore.

9.2c Lipid-Anchored Membrane Proteins Can Act as Switching Devices

Certain proteins are found to be covalently linked to lipid molecules. For many of these proteins, covalent attachment of lipid is required for association with a membrane. The lipid moieties can insert into the membrane bilayer, effectively **anchoring** their linked proteins to the membrane. Some proteins with covalently linked lipid normally behave as soluble proteins; others are integral membrane proteins and remain membrane associated even when the lipid is removed. Covalently bound lipid in these latter proteins can play a role distinct from membrane anchoring. In many cases, attachment to the membrane via the lipid anchor serves to modulate the activity of the protein.

An interesting facet of lipid anchors is that they are transient. Lipid anchors can be reversibly attached to and detached from proteins. This provides a “switching device” for altering the affinity of a protein for the membrane. Reversible lipid anchoring is one factor in the control of *signal transduction pathways* in eukaryotic cells.

Four different types of lipid-anchoring motifs have been found to date. These are **amide-linked myristoyl** anchors, **thioester-linked fatty acyl** anchors, **thioether-linked prenyl** anchors, and **amide-linked glycosyl phosphatidylinositol** anchors. Each of these anchoring motifs is used by a variety of membrane proteins, but each nonetheless exhibits a characteristic pattern of structural requirements.

Amide-Linked Myristoyl Anchors Myristic acid may be linked via an amide bond to the α -amino group of the N-terminal glycine residue of selected proteins (Figure 9.23a). The reaction is referred to as ***N*-myristoylation** and is catalyzed by *myristoyl-CoA:protein N-myristoyltransferase*, known simply as **NMT**. *N*-Myristoyl-anchored proteins include the catalytic subunit of *cAMP-dependent protein kinase*, the *pp60^{src} tyrosine kinase*, the phosphatase known as *calcineurin B*, the α -subunit of *G proteins* (involved in GTP-dependent transmembrane signaling events), and the *gag proteins* of certain retroviruses (including the HIV-1 virus that causes AIDS).

Thioester-Linked Fatty Acyl Anchors A variety of cellular and viral proteins contain fatty acids covalently bound via ester linkages to the side chains of cysteine and sometimes to serine or threonine residues within a polypeptide chain (Figure 9.23b). This type of fatty acyl chain linkage has a broader fatty acid specificity than *N*-myristoylation. Myristate, palmitate, stearate, and oleate can all be esterified in this way, with the C_{16} and C_{18} chain lengths being most commonly found. Proteins anchored to membranes via fatty acyl thioesters include *G-protein-coupled receptors*, the *surface glycoproteins* of several viruses, the *reggie* proteins of nerve axons, and the *transferrin receptor* protein.

Thioether-Linked Prenyl Anchors As noted in Chapter 8, polyprenyl (or simply prenyl) groups are long-chain polyisoprenoid groups derived from isoprene units. Prenylation of proteins destined for membrane anchoring can involve either **farnesyl** or **geranylgeranyl** groups (Figure 9.23c and d). The addition of a prenyl group typically occurs at the cysteine residue of a carboxy-terminal CAAX sequence of the target protein, where C is cysteine, A is any aliphatic residue, and X can be any amino acid. As shown in Figure 9.23c and d, the result is a thioether-linked farnesyl or geranylgeranyl group. Once the prenylation reaction has occurred, a specific protease cleaves the three carboxy-terminal residues, and the carboxyl group of the now terminal Cys is methylated to produce an ester. All of these modifications appear to be important for subsequent activity of the prenyl-anchored protein. Proteins anchored to membranes via prenyl groups include *yeast mating factors*, the *p21^{ras} protein* (the protein product of the *ras* oncogene) and the *nuclear lamins*, structural components of the lamina of the inner nuclear membrane.

Glycosyl Phosphatidylinositol Anchors Glycosyl phosphatidylinositol, or **GPI**, groups are structurally more elaborate membrane anchors than fatty acyl or prenyl groups. GPI groups modify the carboxy-terminal amino acid of a target protein via an ethanolamine residue linked to an oligosaccharide, which is linked in turn to the inositol moiety of a phosphatidylinositol (Figure 9.23e). The oligosaccharide typically consists of a conserved tetrasaccharide core of three mannose residues and a glucosamine, which can be altered by addition of galactosyl side chains of various sizes and extra phosphoethanolamines, *N*-acetylgalactose, or mannosyl residues (Figure 9.23e). The inositol moiety can also be modified by an additional fatty acid, and a variety of fatty acyl groups are found linked to the glycerol group. GPI groups anchor a wide variety of *surface antigens*, *adhesion molecules*, and *cell surface hydrolases* to plasma membranes in various eukaryotic organisms. GPI anchors have not yet been observed in prokaryotic organisms or plants.

9.3 | How Are Biological Membranes Organized?

Biological membranes are **asymmetric** and heterogeneous structures. The two monolayers of the lipid bilayer have different lipid compositions and different complements of proteins. The membrane composition is also different from place to place across the plane of the membrane. There are clusters of particular kinds of lipids, particular kinds of proteins, and a variety of specific lipid–protein associations and aggregates, all of which serve the functional needs of the cell. We say that both the lipids and the proteins of membranes exhibit lateral heterogeneity and transverse asymmetry. **Lateral heterogeneity** arises when lipids or proteins of particular types cluster in the plane of the membrane, as discussed in Section 9.4. **Transverse asymmetry** refers to different lipid or protein compositions in the two leaflets or monolayers of a bilayer membrane.

Many properties of a membrane depend on its two-sided nature. Properties that are a consequence of membrane “sidedness” include membrane transport that is driven in one direction only, the effects of hormones at the outsides of cells, and the recognition reactions that occur between cells (necessarily involving only the outside surfaces of the cells). The proteins involved in these and other interactions must be arranged asymmetrically in the membrane.

Lipid transverse asymmetry can be seen in the typical animal cell, where the acidic and amine-containing phospholipids, phosphatidylserine (PS), phosphatidic acid (PA), phosphatidylglycerol (PG), and phosphatidylinositol (PI), are enriched in the cytoplasmic leaflet of the plasma membrane, and the choline-containing phospholipids and sphingolipids are enriched in the outer leaflet (Figure 9.24). In the erythrocyte, for example, phosphatidylcholine (PC) comprises about 29% of the total phospholipid in the membrane. Of this amount, 76% is found in the outer monolayer and 24% is found in the inner monolayer.

The inner and outer leaflets of most membranes also differ in degree of unsaturation. In erythrocytes, 35% of outer leaflet phospholipids are saturated and most have less than two unsaturations per lipid. By contrast, the cytoplasmic leaflet is highly enriched in phospholipids with polyunsaturated acyl chains, with the majority of lipids containing four or more unsaturations. Phosphatidylcholine, however, is an exception. Inner leaflet PC is mostly saturated, whereas outer leaflet PC is largely polyunsaturated. Unsaturated lipid chains are much more flexible and fluid than saturated chains, and membranes rich in unsaturation have very different properties, as will be seen in Section 9.4.

Asymmetric lipid distributions are important to cells in several ways. The carbohydrate groups of glycolipids (and of glycoproteins) always face the outside of plasma membranes, where they participate in cell recognition phenomena. Asymmetric lipid distributions may also be important to various integral membrane proteins, which may prefer particular lipid classes in the inner and outer monolayers.

Many proteins contain lipid-binding domains as well as positively charged regions that can interact with the negatively charged headgroups of acidic phospholipids. The resulting ionic protein–lipid interactions can direct cytoplasmic proteins to the plasma membrane, induce membrane protein clustering, and regulate protein conformations and functions.

Figure 9.24 Phospholipids are distributed asymmetrically in most membranes, including the human erythrocyte membrane, as shown here. **(a)** The distribution of phospholipids across the inner and outer leaflets of human erythrocytes. The x -axis values show, for each lipid type, its percentage of the total phospholipid in the membrane. **(b)** The phospholipid compositions of the inner and outer leaflets. Note that the bar chart and pie charts provide complementary information. All percentages in **(a)** and **(b)** are weight percentages. (Adapted from Zachowski, A., 1993. Phospholipids in animal eukaryotic membranes: Transverse asymmetry and movement. *Biochemical Journal* **294**:1–14; and from Andreoli, T. E., 1987. *Membrane Physiology*, 2nd ed. Chapter 27, Table I. New York: Springer.)

Loss of transverse lipid asymmetry has dramatic (and often severe) consequences for cells and organisms. For example, appearance of PS in the outer leaflet of the plasma membrane triggers apoptosis, the programmed death of the cell. Similarly, aging erythrocytes and platelets slowly externalize PS, culminating in engulfment by macrophages. Many disease states, including diabetes and malaria, involve microvascular occlusions that may result in part from alterations of transverse lipid asymmetry.

9.4 What Are the Dynamic Processes That Modulate Membrane Function?

The motions of lipids and proteins in membranes underlie many cell functions. This section describes the nature of these motions and how they affect membrane structure.

9.4a Lipids and Proteins Undergo a Variety of Movements in Membranes

Lipid movements in membranes (Figure 9.25) range from bond vibrations (at 10^{12} per sec), to bilayer undulations (1 to 10^6 per sec), to transverse motion—called flip-flop (roughly one per day to one per sec). Lateral movement of lipids (in the plane of the membrane) is rapid. Adjacent lipids can change places with each other on the order of 10^7 /sec. Thus, a typical phospholipid can diffuse laterally in a membrane at a linear rate of several microns per second. At that rate, a phospholipid molecule travels from one end of a bacterial cell to the other in less than a second or traverses a typical animal cell in a few minutes.

Many membrane proteins move laterally (through the plane of the membrane) at a rate of a few microns per minute. On the other hand, some integral membrane proteins are more restricted in their lateral movement, with diffusion rates of about 10 nm per sec or even slower. Slower motion is likely for proteins that associate and bind with each other and for proteins that are anchored to the cytoskeleton, a complex latticelike structure that maintains the cell's shape and assists in the controlled movement of various substances through the cell.

Figure 9.25 Lipid motions in the membrane and their characteristic frequencies. (Adapted from Gawrisch, K., 2005. The dynamics of membrane lipids. In *The Structure of Biological Membranes*, Chapter 4, Figure 4.1, Yeagle, P. L., ed., 2005. Boca Raton: CRC Press.)

Flippases, Floppases, and Scramblases: Proteins That Redistribute Lipids across the Membrane Proteins that can flip and flop phospholipids from one side of a bilayer to the other have also been identified in several tissues (Figure 9.26). Three classes of such proteins are known:

1. ATP-dependent **flippases** that transport PS, and to a lesser extent PE, from the outer leaflet to the inner leaflet of the plasma membrane
2. ATP-dependent **floppases** that transport a variety of amphiphilic lipids, especially cholesterol, PC, and sphingomyelin, from the inner leaflet to the outer leaflet
3. Bidirectional, Ca^{2+} -activated (but ATP-independent) **scramblases** that function to randomize lipids and thus degrade transverse asymmetry

The ATP-dependent flippases and floppases belong to two large and unrelated active transport systems: the ATP-binding cassette (ABC) transporters (see Section 9.10) and the P4-ATPases, a subclass of the P-type ATPases (see Section 9.8). Both families hydrolyze ATP to drive transport, although they employ different mechanisms to do so. These proteins reduce the half-time for phospholipid movement across a membrane from days to a few minutes or less. Approximately one ATP is consumed per lipid transported by flippases and floppases. Energy-dependent lipid flippase activity is essential for the creation and maintenance of transverse lipid asymmetries. A number of diseases have been linked to defects in flippases and floppases. Tangier disease causes accumulation of high concentrations of cholesterol in various tissues and leads to cardiovascular problems. Infants with respiratory distress syndrome produce low amounts of lung surfactant (a mix of lipids) and typically die a few days after birth. Both of these diseases involve flippase or floppase defects.

9.4b Membrane Lipids Can Be Ordered to Different Extents

The phospholipids and sterols of membranes can adopt different structures depending on the exact lipid and protein composition of the membrane and on the temperature. At low temperatures, bilayer lipids are highly ordered, forming a **gel phase** with the acyl chains nearly perpendicular to the plane of the membrane plane

Figure 9.26 The actions of flippases, floppases, and scramblases. **(a)** Phospholipids can be flipped, flopped, or scrambled across a bilayer membrane by the action of flippase, floppase, and scramblase proteins. **(b)** When, by normal diffusion through the bilayer, the lipid encounters one of these proteins, it can be moved quickly to the other face of the bilayer. **(c)** Structure of a flippase (PDB id = 7KYC). **(d)** Structure of a floppase (PDB id = 6BPP). **(e)** Structure of a scramblase (PDB id = 7JLP).

(Figure 9.27). In this state—called the **solid-ordered state** (or **S_o state**)—the lipid chains are tightly packed and undergo relatively little motion. The lipid chains are in their fully extended conformation, the surface area per lipid is minimal, and the bilayer thickness is maximal. At higher temperatures, the acyl chains undergo much more motion, with rotations around the acyl chain C—C bonds and significant large-scale disordering of the acyl chains. The membrane is then said to be in a **liquid crystalline phase** or **liquid-disordered state** (**L_d state**) (Figure 9.27). In this less ordered state, the surface area per lipid increases and the bilayer thickness decreases by 10% to 15%. Under most conditions, the transition from the gel phase to the liquid crystalline phase is a true **phase transition**, and the temperature at which this change occurs is referred to as a **transition temperature** or **melting temperature** (**T_m**).

The sharpness of the transition in pure lipid preparations shows that the phase change is a cooperative behavior. This is to say that the behavior of one or a few molecules affects the behavior of many other molecules in the vicinity. The sharpness of the transition then reflects the number of molecules that are acting in concert. Sharp transitions involve large numbers of molecules all melting together.

Phase transitions have been characterized in a number of different pure and mixed lipid systems. Table 9.2 shows a comparison of the transition temperatures observed for

Figure 9.27 The gel-to-liquid crystalline phase transition, which occurs when a membrane is warmed through the transition temperature, T_m . In the transition, the surface area increases, the membrane thickness decreases, and the mobility of the lipid chains increases dramatically. Membrane phase transitions can be characterized by measuring the rate of heat absorption by a membrane sample in a calorimeter. Pure, homogeneous bilayers (containing only a single lipid component) give sharp calorimetric peaks. As membrane heterogeneity increases, the calorimetric peaks broaden. Below phase transitions, lipid chains primarily adopt the anti conformation. Above the phase transition, lipid chains have absorbed a substantial amount of heat. This is reflected in the adoption of higher-energy conformations, including the gauche conformations shown.

Table 9.2 Phase Transition Temperatures for Phospholipids in Water	
Phospholipid	Transition Temperature (T_m), °C
Dimyristoyl phosphatidylcholine (Di 14:0)	23.6
Dipalmitoyl phosphatidylcholine (Di 16:0)	41.4
Distearoyl phosphatidylcholine (Di 18:0)	58
1-Stearoyl-2-oleoyl-phosphatidylcholine (1-18:0, 2-18:1 PC)	3
Dioleoyl phosphatidylcholine (Di 18:1 PC)	−22
Egg phosphatidylcholine (Egg PC)	−15
Dipalmitoyl phosphatidic acid (Di 16:0 PA)	67
Dipalmitoyl phosphatidylethanolamine (Di 16:0 PE)	63.8
Dipalmitoyl phosphatidylglycerol (Di 16:0 PG)	41.0

Adapted from Jain, M., and Wagner, R. C., 1980. *Introduction to Biological Membranes*. New York: John Wiley and Sons; and Martonosi, A., ed., 1982. *Membranes and Transport*, Vol. 1. New York: Plenum Press.

several different phosphatidylcholines with different fatty acyl chain compositions. General characteristics of bilayer phase transitions include the following:

1. The transitions are always endothermic; heat is absorbed as the temperature increases through the transition (Figure 9.27).
2. Particular phospholipids display characteristic transition temperatures (T_m). As shown in Table 9.2, T_m increases with chain length, decreases with unsaturation, and depends on the nature of the polar head group.
3. For pure phospholipid bilayers, the transition occurs over a narrow temperature range. The phase transition for dimyristoyl lecithin has a peak width of about 0.2°C.
4. Native biological membranes also display characteristic phase transitions, but these are broad and strongly dependent on the lipid and protein composition of the membrane.
5. With certain lipid bilayers, a change of physical state referred to as a *pretransition* occurs 5° to 15°C below the phase transition itself. These pretransitions involve a tilting of the hydrocarbon chains.
6. A volume change is usually associated with phase transitions in lipid bilayers.
7. Bilayer phase transitions are sensitive to the presence of solutes that interact with lipids, including multivalent cations, lipid-soluble agents, peptides, and proteins.

Cells adjust the lipid composition of their membranes to maintain proper fluidity as environmental conditions change.

In addition to the solid-ordered (S_o) and liquid-disordered (L_d) states, model lipid bilayers can exhibit a third structural phase if the membrane contains sufficient sphingolipid and cholesterol. The **liquid-ordered (L_o) state** (Figure 9.28) is characterized by a high degree of acyl chain ordering (like the S_o state) but has the translational disorder characteristic of the L_d state. Lipid diffusion in the L_o phase is about twofold to threefold slower than in the L_d phase. Biological membranes are hypothesized to contain regions equivalent to all three phases of model membranes: S_o , L_d , and L_o .

Dynamic Exchange of Lipids and Proteins with Membrane Domains The membrane heterogeneity described in Section 9.3 is the result of **lateral organization**. The plasma membranes of mammalian cells are organized into distinct domains of differing protein and lipid composition. There is a continuous and highly dynamic exchange between lipid and protein monomers, nanoscale lipid and protein clusters, and microscale higher-order structures that orchestrates protein function (Figure 9.29a). Nanoscale domains (5–100 nm diameter) typically consist of a few dozen to a few hundred lipid molecules and just a few proteins. Microscale domains may extend over several micrometers.

Figure 9.28 Image from a molecular dynamics simulation of a model bilayer composed of dipalmitoylphosphatidylcholine and cholesterol, showing a phase separation of liquid disordered (L_d) and liquid ordered (L_o) nanodomains. (Adapted with permission from Figure 1 of Javanainen, M., Martinez-Seara, H., and Vattulainen, I., 2017. Nanoscale membrane domain formation driven by cholesterol. *Scientific Reports* 7:1143. Image provided by Matti Javanainen.)

The maintenance of these domains, and the exchange of lipids and proteins between them, is regulated by factors both intrinsic and extrinsic to the membrane. Lipids (glycerophospholipids, sphingolipids, and cholesterol) may self-associate in clusters (Figure 9.29b), and membrane proteins may act to organize domain components and structures. **Tetraspanin** proteins, for example (Figure 9.29c) act as scaffolding proteins to cluster and organize other proteins.

Tetraspanins are evolutionarily conserved proteins (there are 33 in the human body), involved in adhesion, migration, and signaling. Tetraspanins consist of four transmembrane α -helical domains, two small intracellular tails, a small intracellular loop, and two extracellular loops (Figure 9.29d). Tetraspanin membrane domains are between 100 nM and 200 nM in diameter and contain fewer than ten tetraspanin proteins. Tetraspanin monomers and dimers exchange with tetraspanin nanodomains. Partner protein interactions occur within or at the border of these nanodomains. Loss of these domains leads to cellular defects and the deregulation of signal pathways.

Cortical actin filaments (F-actin and actin-binding proteins, Figure 9.29e) of the cytoskeleton attach to the inner leaflet of the plasma membrane, and energy-driven processes organize these actin filaments that affect local membrane composition and shape. In turn, membrane composition can regulate cytoskeletal dynamics—a dynamic interplay between membrane organization and the actin cytoskeleton that provides the cell with a stable yet flexible cell surface that can continuously adapt to its environment. The actin cytoskeleton is a rigid extrinsic organizer that forms fence-like structures underneath the membrane that account for hop diffusion (see following section). At the same time, the continuous remodeling of cortical actin affects the dynamic exchange of membrane organization. Like instruments in a symphony, playing together but each changing leads during a piece, all these lipid–protein interactions play different structural and functional roles at different times in biological membranes.

Figure 9.29 Dynamic exchange of domains in membranes involves lipid clustering, protein clusters organized by tetraspanins, as well as lipid and protein clusters assembled by cortical actin.

(a) Nanodomains and microdomains of lipids and proteins in the plasma membrane are in a dynamic equilibrium with lipid and protein monomers. (b) Lipids of various types can form clusters in the plane of the membrane. (c) Tetraspanins (blue) can induce clustering of multiple proteins (gray objects) in membrane nanodomains. (d) Structure of tetraspanin CD81 (PDB id = 5TCX). (e) Actin components on the cytoplasmic face of a membrane (termed *cortical actin*) can organize lipid and protein clusters in the membrane.

Lateral Membrane Diffusion Is Restricted by Barriers and Fences A variety of studies of lateral diffusion rates in membranes have shown that membrane proteins and lipids in plasma membranes diffuse laterally at a rate 5 to 50 times slower than those of artificial lipid membranes. Why should this be? Part of the answer has come from **single particle tracking** experiments (Figure 9.30a), which reveal that lipids and at least some membrane proteins tend to undergo **hop diffusion**, such that they can diffuse freely within a membrane “compartment” for a time and then hop to an adjacent compartment, where the process repeats. Akihiro Kusumi and colleagues have proposed the **membrane–skeleton fence** model to explain this behavior, suggesting that certain proteins that comprise the **cytoskeleton**—a network of proteins on the cytoplasmic face of the plasma membrane—restrict the lateral diffusion of other membrane proteins (Figure 9.30b). The fence proteins may include *spectrin*, a filamentous cytoskeletal protein in red blood cells, and *actin*, a cytoskeletal protein that is ubiquitous in eukaryotic cells. The single particle tracking experiments show that lipid molecules are typically confined within fenced compartments for approximately 13 ms to 15 ms, whereas transmembrane proteins are typically confined for 45 ms to 65 ms. Even lipids in the outer leaflet of the plasma membrane undergo hop diffusion, leading Kusumi and colleagues to postulate that transmembrane proteins act as rows of pickets extending across both monolayers in these membrane fences. Fences thus define regions of relatively unrestricted lipid diffusion.

Lipids and Proteins Direct Dynamic Membrane Remodeling and Curvature The complex shapes of cells and organelles are the result of forces that operate on their membranes, and these forces in turn are orchestrated by lipids and proteins. Membranes change their shapes in special ways during movement, cell division, and other cellular events. This dynamic membrane remodeling is also accomplished by the interplay of lipids and proteins. The various membrane subdomains with particular curvatures have precise and specialized biological properties and functions.

Figure 9.30 Motions of a single (fluorescently labeled) lipid molecule on the surface of a cell can be measured by video fluorescence microscopy. **(a)** Video recording at 40,000 frames per second yields a time resolution of 25 μ s. Data collected over 62 ms (a total of 2500 frames) show that a lipid diffuses rapidly within small domains (defined by colors) and occasionally jumps or hops to an adjacent region (shown as a color change). (Adapted from Kusumi, A., et al., 2005. Paradigm shift of the plasma membrane concept from the two-dimensional continuum fluid to the partitioned fluid: High-speed single-molecule tracking of the membrane molecules. *Annual Review of Biophysics and Biomolecular Structure* 34:351–378.) **(b)** Video microscopy studies of single lipid molecule movement in membranes are consistent with a compartmentalized model for the membrane, in which lipids and proteins undergo short-term diffusion within fenced compartments, with occasional hops to adjacent compartments. Akihiro Kusumi has suggested that elements of the cytoskeleton may define the fence boundaries at the membrane.

Figure 9.31 Membrane curvature can occur by several different mechanisms, including (a) changes in lipid composition, (b) insertion of membrane proteins that have intrinsic curvature or that oligomerize, (c) insertion of amphipathic helices into one leaflet of the bilayer, (d) interaction of the bilayer with molecular scaffolding proteins, or (e) changes induced by the cytoskeletal filaments inside the cell. (Adapted from McMahon, H. T., and Gallop, J. L., 2005. Membrane curvature and mechanisms of dynamic cell membrane remodeling. *Nature* 438:590–596.)

There are several ways to induce curvature in a membrane. Lipids can influence or accommodate membrane curvature (Figure 9.31a), either because of lipid molecule geometry or because of an imbalance in the number of lipids in the inner and outer leaflets of the bilayer. (In a liposome of 50 nm diameter, there is 56% more lipid in the outer leaflet than in the inner leaflet.) Integral membrane proteins with conical shapes can promote membrane curvature (Figure 9.31b). The structure of a voltage-gated K^+ channel is an example of a shape conducive to membrane curvature (see Figure 9.31). Proteins of the cytoskeleton, such as actin, typically contact the plasma membrane and can generate curvature by rearrangements of their own structure. Moreover, motor proteins moving along filaments of the cytoskeleton can generate curvature in the membrane. **Scaffolding proteins**, which can bind on either side of the plasma membrane, can influence membrane curvature in many ways. For example, BAR domains are dimeric, banana-shaped structures (Figure 9.32) that bind preferentially to and stabilize curved regions of the plasma membrane. Finally, amphipathic α -helices can insert into bilayers, parallel to the membrane surface, thus forcing curvature on the membrane (Figure 9.31c). N-BAR domains are BAR domains that have an N-terminal α -helix preceding the BAR domain. The helix typically inserts to induce curvature, and the BAR domain binds to stabilize the curved structure. Harvey McMahon and his colleagues have proposed a structure (Figure 9.32b) for N-BAR domain-mediated membrane curvature by *endophilin-A1*, a protein found at synapses and implicated in the formation of synaptic vesicles. Membrane curvature is essential to a variety of cellular functions, including cell division, viral budding, and the processes of endocytosis and exocytosis, described in the next section.

Caveolins and Caveolae Respond to Plasma Membrane Changes Caveolae are flask-shaped indentations in plasma membranes. Caveolae participate in **mechanosensation**, the detection and sensing of mechanical forces at the membrane, and **mechanotransduction**, the conversion of mechanical forces into biochemical signals that result in cell responses that regulate cell growth, differentiation, cell shape, and cell death. Caveolae (Figure 9.33) are rich in cholesterol, sphingolipids, and **caveolin**, an integral membrane protein of 22,000 MW. There are three members of the caveolin family. CAV1 and CAV2 are found in endothelial, fibrous, and adipose (fat) tissue, whereas CAV3 is unique to skeletal muscle. Caveolins form homodimers in the plasma membrane, with both N- and C-termini oriented toward the cytosolic face of the membrane. The C-terminal domain has several palmitoyl lipid anchors and is separated from the N-terminal oligomerization domain by a 33-residue intramembrane hairpin domain. A typical caveolar structure consists of about 144 caveolin molecules, with up to 20,000 cholesterol molecules.

Vesicle Formation and Fusion Are Essential Membrane Processes The membranes of cells are not static. Normal cell function requires that the various membrane-enclosed compartments of the cell constantly reorganize and exchange proteins, lipids, and other materials. These processes, and others such as cell division, exocytosis,

Figure 9.32 Model of BAR domain binding to membranes. (a) The classical model for binding of BAR domains to membranes (PDB id = 2C08). (b) A model for membrane binding of endophilin-A1, with amphiphilic helices inducing curvature that is stabilized by BAR domain binding. (Adapted from Gallop, J. L., et al., 2006. Mechanism of endophilin N-BAR domain-mediated membrane curvature. *The EMBO Journal* 25:2898–2910. Image in (b) kindly provided by Harvey T. McMahon.)

endocytosis, and viral infection, all involve either fusion of one membrane with another or budding and separation of a vesicle from a membrane. Eukaryotic organelles communicate with one another by the exchange of *trafficking vesicles*. Vesicles are generated at a precursor membrane, transported to their destination, and then fused with the target compartment (Figure 9.34). Although the organelles involved in these processes are diverse—endoplasmic reticulum, Golgi, endosomes, and others—the basic reactions of budding and fusion are accomplished by protein families and multiprotein complexes that have been conserved throughout eukaryotic evolution. The molecular events of exocytotic release of neurotransmitters into the synapses of nerve cells are good examples of such processes.

Neurons communicate with one another by converting electrical signals into chemical signals and back again. When electrical signals arrive at the synapse, vesicles containing neurotransmitters (such as acetylcholine) fuse with the plasma membrane, releasing the neurotransmitters into the synaptic cleft. The binding of neurotransmitters to receptors

Figure 9.35 The domain structure of the SNARE protein families. **(a)** A variety of N-terminal domains are found in Q_a SNARE proteins, including the three-helix bundle of syntaxin-1 (PDB id = 1BR0); **(b)** Q_{bc} SNAREs (such as SNAP-25) are anchored in the membrane by palmitic acid lipid anchors; **(c)** Many R SNAREs contain small globular N-terminal domains such as Vam7, a PX-homology domain (PDB id = 1OCS). (Adapted from Jahn, R., and Scheller, R. H., 2006. SNAREs—engines for membrane fusion. *Nature Reviews Molecular Cell Biology* 7:631–643.)

on an adjacent neuron generates an electrical signal that is passed along. The fusion of vesicles with the plasma membrane is directed by **SNAREs**—a family of proteins that snare vesicles to initiate the fusion process. (The acronym, a somewhat strained effort to describe their function cleverly, stands for *soluble N-ethylmaleimide-sensitive factor attachment protein receptor*.) SNAREs are small proteins with a simple domain structure (Figure 9.35) that includes a **SNARE motif**, consisting of 60 to 70 residues of classical 7-residue repeats (see Chapter 6). These SNARE domains form a four-helix bundle that bridges two membranes, drawing them together in the first stage of membrane fusion. The N-terminal domains are variable across the SNARE family, but at their C-termini most SNAREs have a single transmembrane domain joined to the SNARE motif by a short linker. **Syntaxin-1** (known as a **Q_a SNARE**, for a conserved glutamine) has an N-terminal three-helix bundle, whereas **SNAP-25** (known as a **Q_{bc} SNARE**) consists of two SNARE domains joined by a linker with two palmitoyl lipid anchors (Figure 9.35). **Synaptobrevin** (known as an **R SNARE**, for a conserved arginine (R)) consists of a small N-terminal domain, in addition to its SNARE and transmembrane domains.

The fusion of a vesicle with the plasma membrane is a multistep process (Figure 9.36). When a neurotransmitter-laden vesicle approaches the plasma membrane, syntaxin-1 and SNAP-25 on the plasma membrane join with synaptobrevin on the vesicle to form a four-helix bundle that bridges the two membranes, drawing them together in the first stage of membrane fusion, termed *Priming Stage I*. The binding of **complexin**, a small helical protein, clamps the complex so that it is poised for membrane fusion but is unable to complete the process. Arrival of an action potential (electrical signal—see Chapter 32) triggers the flow of Ca^{2+} ions into the cell through channel proteins, and the binding of Ca^{2+} ion to **synaptotagmin** displaces complexin and promotes the joining of the membranes (to form *Priming Stage II*) and the formation of a fusion pore. The complexin clamp (Figure 9.36) ensures that neurotransmitter release can occur in an instant following Ca^{2+} influx because the slow steps of SNARE assembly have already been completed.

Figure 9.36 SNARE complex assembly and its control in plasma membrane fusion. Step 1: Q SNAREs (syntaxin-1 and SNAP-25), organized in clusters, assemble into acceptor complexes in the plasma membrane. Step 2: Acceptor complexes interact with synaptobrevin in an approaching vesicle, forming a four-helical Priming Stage I. Step 3: Membrane fusion and pore formation are prevented by binding of complexin. Step 4: Arrival of an action potential (nerve impulse) triggers displacement of complexin by synaptotagmin, initiating fusion and pore formation. Step 5: Upon completion of the fusion process, the *trans* complex relaxes. Step 6: SNAREs are redistributed to their respective membrane domains and vesicles are reformed. (Adapted from Jahn, R., and Scheller, R. H., 2006. SNAREs—engines for membrane fusion. *Nature Reviews Molecular Cell Biology* 7:631–643.)

9.5 | How Does Transport Occur across Biological Membranes?

Transport processes are vitally important to all life forms, because all cells must exchange materials with their environment. Cells obviously must have ways to bring nutrient molecules into the cell and ways to send waste products and toxic substances out. Also, inorganic electrolytes must be able to pass in and out of cells and across organelle membranes. All cells maintain **concentration gradients** of various metabolites across their plasma membranes and also across the membranes of intracellular organelles. By their very nature, cells maintain a very large amount of potential energy in the form of such concentration gradients. Sodium and potassium ion gradients across the plasma membrane mediate the transmission of nerve impulses and the normal functions of the brain, heart, kidneys, and liver, among other organs. Storage and release of calcium from cellular compartments controls muscle contraction as well as the response of many cells to hormonal signals. High acid concentrations in the stomach are required for the digestion of food. Extremely high hydrogen ion gradients are maintained across the plasma membranes of the mucosal cells lining the stomach in order to maintain high acid levels in the stomach.

We shall consider the molecules and mechanisms that mediate these transport activities. In nearly every case, the molecule or ion transported is water soluble, yet moves

Figure 9.37 Passive diffusion of an uncharged species across a membrane depends only on the concentrations (C_1 and C_2) on the two sides of the membrane. The concentration ratio shown is for movement from side 1 (initial state) to side 2 (final state). For movement in the opposite direction, the concentration ratio would be the inverse.

Figure 9.38 The passive diffusion of a charged species across a membrane depends on the concentration and also on the charge of the particle, Z , and the electrical potential difference across the membrane, $\Delta\psi$ for movement from side 1 (initial state) to side 2 (final state).

across the hydrophobic, impermeable lipid membrane at a rate high enough to serve the metabolic and physiological needs of the cell. This perplexing problem is solved in each case by a specific transport protein. The transported species either diffuses through a channel-forming protein or is carried by a carrier protein. Transport proteins are all classed as **integral membrane proteins**.

From a thermodynamic and kinetic perspective, there are only three types of membrane transport processes: *passive diffusion*, *facilitated diffusion*, and *active transport*. To be thoroughly appreciated, membrane transport phenomena must be considered in terms of thermodynamics. Some of the important kinetic considerations also will be discussed.

9.6 | What Is Passive Diffusion?

Passive diffusion is the simplest transport process. In passive diffusion, the transported species moves across the membrane in the thermodynamically favored direction without the help of any specific transport system/molecule. For an uncharged molecule, passive diffusion is an entropic process, in which movement of molecules across the membrane proceeds until the concentration of the substance on both sides of the membrane is the same. For an uncharged molecule, the free energy difference between side 1 and side 2 of a membrane (Figure 9.37) is given by

$$\Delta G = G_2 - G_1 = RT \ln \left(\frac{[C_2]}{[C_1]} \right) \quad (9.1)$$

The difference in concentrations, $[C_2] - [C_1]$, is termed the *concentration gradient*, and ΔG here is the *chemical potential difference* for movement from side 1 to side 2.

For a charged species, the situation is slightly more complicated. In this case, the movement of a molecule across a membrane depends on its **electrochemical potential**. This is given by

$$\Delta G = G_2 - G_1 = RT \ln \left(\frac{[C_2]}{[C_1]} \right) + Z\mathcal{F}\Delta\psi \quad (9.2)$$

where Z is the **charge** on the transported species, $\mathcal{F}$ is **Faraday's constant** (the charge on 1 mole of electrons = 96,485 coulombs/mol = 96,485 joules/volt-mol, since 1 volt = 1 joule/coulomb), and $\Delta\psi$ is the electric potential difference (that is, voltage difference) across the membrane. The second term in the expression thus accounts for the movement of a charge across a potential difference. Note that the effect of this second term on ΔG depends on the magnitude and the sign of both Z and $\Delta\psi$. The potential difference term should always be stated as final state potential minus initial state potential.

For example, as shown in Figure 9.38, if side 2 has a higher potential than side 1 (so that $\Delta\psi$ is positive), for a negatively charged ion the term $Z\mathcal{F}\Delta\psi$ makes a negative contribution to ΔG . In other words, the negative charge is spontaneously attracted to the more positive potential—and ΔG is negative. In any case, if the sum of the two terms on the right side of Equation 9.2 is a negative number, transport of the ion in question from side 1 to side 2 would occur spontaneously. The driving force for passive transport is the ΔG term for the transported species itself.

9.7 | How Does Facilitated Diffusion Occur?

The transport of many substances across simple lipid bilayer membranes via passive diffusion is far too slow to sustain life processes. On the other hand, the transport rates for many ions and small molecules across actual biological membranes are much higher than anticipated from passive diffusion alone. This difference is due to specific proteins in the cell membranes that *facilitate* the transport of these species across the membrane. Proteins capable of effecting **facilitated diffusion** of a variety of solutes are present in essentially all natural membranes. Such proteins have two features in common: (1) They facilitate net movement of solutes only in the thermodynamically

avored direction (that is, $\Delta G < 0$), and (2) they display a measurable affinity and specificity for the transported solute. Consequently, facilitated diffusion rates display **saturation behavior**, like that seen for ligand binding to a protein (see Figure 5.26). Such behavior provides a simple means for distinguishing between passive diffusion and facilitated diffusion experimentally. The dependence of transport rate on solute concentration takes the form of a rectangular hyperbola (Figure 9.39), so the transport rate approaches a limiting value, $V_{\max}$, at a very high solute concentration. Figure 9.39 also shows the graphical behavior exhibited by simple passive diffusion. Because passive diffusion does not involve the formation of a specific solute–protein complex, the plot of rate versus concentration is linear, not hyperbolic.

9.7a Membrane Channel Proteins Facilitate Diffusion

Membrane transport channels carry out facilitated diffusion. In contrast to active transport systems (or pumps) like Na^+ , K^+ -ATPase and Ca^{2+} -ATPase, channels simply enable the (energetically passive) downhill movement of ions and other molecules. However, active pumps and most channels share one fundamental property: The ability to transport species in a selective manner. Molecular selectivity is crucial to the operation of both pumps and channels. The human proteome lists 400 ion channels.

The membrane channel structures determined to date have revealed some of nature's strategies for moving ions and molecules across biological membranes. Channel composition can take several forms. A single-channel pore can be formed from dimers, trimers, tetramers, or pentamers of protein subunits (for example, channels for Na^+ , K^+ , Mg^{2+} , and glutamate; see Table 9.3). On the other hand, multimeric assemblies in which each subunit has its own pore have been described (in channels for Cl^- , NH_3 , water, and glycerol). Several recurring themes are apparent from the channel structures studied to date:

- Some channels are **selective** for a particular ion or molecule. Others select either for cations or for anions, and some are nonselective.
- Channels can be **gated**—that is, they can open or close in response to a triggering signal. Some channels are **voltage gated** and open and close in response to a change in membrane electrical potential (that is, voltage). Other channels are **ligand gated**, opening or closing in response to binding of an ion, a small organic molecule, or even a protein.
- Channels that are ion selective usually have pores lined with (oppositely) charged amino acids. Cation channels are lined with negatively charged residues; anion channels are lined with positively charged residues.
- Ions may flow through channels either in a hydrated or unhydrated state, depending on the width of the channel. Wider pores are often unselective and accept ions in their hydrated states. Narrower pores lined with charged amino acids are more likely to be highly selective.

Lineweaver–Burk

Hanes–Woolf

Figure 9.39 Passive diffusion and facilitated diffusion may be distinguished graphically. The plots for facilitated diffusion are similar to plots of enzyme-catalyzed processes and they display saturation behavior.

Table 9.3 Subunit Composition and Pore Structure of Membrane Channels

Channel	ASIC	KcsA NaK Glutamate	CorA	CIC	Amt-1 AmtB	AQP1, AQP2, Glpf
Mg^{2+}	Na^+	K^+ Na^+ Glutamate	Mg^{2+}	Cl^-	NH_3	H_2O Glycerol
Transported Species						

The key questions for any channel protein are:

- How does the channel open and close?
- How does gating occur—that is, how is a voltage change sensed or how does a triggering ligand bind?
- How is voltage sensing or ligand binding **coupled** to channel opening and closing?

These recurring themes and key questions are illustrated particularly well by the K^+ channels characterized largely by Roderick MacKinnon and his colleagues.

Potassium Channels Combine High Selectivity with High Conduction Rates Potassium transport (that is, conduction) is essential for many cell processes, including regulation of cell volume, electrical impulse formation (in electrically excitable cells, such as neurons), and secretion of hormones; all cells thus conduct K^+ ions across the cell membrane. Potassium channels are facilitated diffusion devices, conducting K^+ down the electrochemical gradient for K^+ . Whether found in bacteria, archaea, plants, or animals, all known potassium channels are members of a single protein family. Potassium channels have two important characteristics: They are highly selective for K^+ ions over Na^+ ions, and they conduct K^+ ions at very high rates (almost as fast as any entity can diffuse in water—the so-called diffusion limit).

The structure of *KcsA*, from *Streptococcus lividans*, is typical of the simpler prokaryotic K^+ channels (Figure 9.40). The structure consists of four identical subunits, and, facing the cytosol is a water-filled pore that traverses more than half of the membrane bilayer, ending at the selectivity filter. A hydrated K^+ ion is suspended in the center of the pore. Each subunit consists of two transmembrane helices (S1 and S2, the outer and inner helices, respectively), with an intervening reentrant loop consisting of a 10-residue pore helix and a 5-residue β -strand that is one quarter of the selectivity filter. The inner (S2) helices form an inverted “teepee” with the shorter pore helices arranged within.

In contrast to the simple prokaryotic K^+ channels, the mammalian voltage-gated potassium channels involved in nerve and muscle function are more complex, with each tetramer subunit consisting of six transmembrane helical segments (S1–S6). Helices S1–S4 form the voltage sensor domain, whereas the S5–S6 domain is analogous to the transmembrane helices of *KcsA* and forms the transport channel.

The selectivity filter in *KcsA* (Figure 9.40) consists of four pentapeptides, one from each subunit, with the sequence TVGYG. The backbone carbonyls of the first four residues and the threonine side-chain oxygen—evenly spaced—face the center of the pore. These oxygens create four possible K^+ -binding sites. In each site, a bound, dehydrated K^+ is surrounded by eight oxygens from the protein: four above and four below. The arrangement of protein oxygens at each site is very similar to the arrangement of water molecules around a hydrated K^+ . This simple structure is strikingly selective for K^+ . The physical basis for selection between K^+ and Na^+ is the atomic radius—1.33 Å for K^+ and 0.95 Å for Na^+ . Still, K^+ channels select for K^+ over Na^+ by a factor of more than a thousand!

Figure 9.40 Structure of the *KcsA* potassium channel from *Streptococcus lividans* (PDB id = 1K4C). (a) The four identical subunits of the channel, which surround a central pore, are shown in different colors. (b) Each subunit contributes three α -helices (blue, green, red) to the tetramer structure. (c) The selectivity filter is made from loops from each of the subunits, two of which are shown here. (d) The tetrameric channel, as viewed through the pore. In (a), (b), and (c), the cytosolic side is at the top.

Figure 9.41 Model for inward and outward transport through the KcsA potassium channel. The selectivity filter in the channel contains four K^+ -binding sites, only two of which are filled at any time.

As K^+ moves through the KcsA channel, there are, on average, two K^+ ions bound in the selectivity filter at any given time, either in positions 1 and 3 or positions 2 and 4 (with water molecules occupying the other positions). Ions can move in either direction across the channel, depending on the existing electrochemical gradient. One K^+ enters the channel from one side as a different ion exits on the other side. The cycle of steps for inward or outward movement is shown in Figure 9.41.

High selectivity, along with high conduction rates, seems at first paradoxical. If K^+ ions bind too tightly in the filter, they could not move quickly through the pore. Two factors keep the binding just tight enough, but not too tight: (1) repulsion between the closely spaced K^+ ions at their two sites and (2) a conformational change induced by K^+ binding.

The KcsA channel is gated by intracellular pH. It is closed at neutral pH and above, and it opens at acidic pH. What is the conformational change that opens this and other K^+ channels? After comparing the closed-pore conformation of KcsA with the open-pore conformation of the related MthK channel (Figure 9.42), MacKinnon has proposed that helix bending and rearrangement deep in the membrane opens K^+ channels.

The mammalian K^+ channel is voltage gated. In this more complex structure (Figure 9.43), helix S4 contains a series of five positively charged Arg residues, spaced every three residues. These five residues all face the outside surface of the membrane in the open state of the channel. MacKinnon and coworkers have postulated that channel closing involves movement of the S4 helix inward, which pushes down on the short S4-S5 linker helix, which induces a conformation change in S5 and S6, thus closing the channel.

9.7b The *Bacillus cereus* NaK Channel Uses a Variation on the K^+ Selectivity Filter

Could the K^+ channel selectivity filter be modified to accommodate other ions, for instance Na^+ ? A comparison of amino acid sequences from a variety of ion channels (Figure 9.44) shows that this is indeed the case. Variations on the TVGYG filter

Figure 9.42 Comparison of the closed (PDB id = 1K4C) and open (PDB id = 1LNQ) states of the MthK potassium channel. The inner helices obstruct the central pore in the closed conformation. However, bending at a glycine residue near the center of the membrane splays the inner helices outward from the channel center, allowing free access for ions between the cytosol and the selectivity filter. This critical Gly residue is conserved in most K^+ channel sequences, making this a likely gating mechanism for most K^+ channels.

Sequence of selectivity filter	Selective for
T V G Y G D L Y P	K ⁺
T V G D G N F S P	Na ⁺ , K ⁺
L T G E D W N S V	Ca ²⁺

Figure 9.44 Ion selectivity in cation channels is a function of peptide sequence of the selectivity filter. Conserved glycines in the TVGYG motif of the KcsA potassium channel are shown in red. Amino acids that are chemically similar are yellow. From top to bottom, the selectivity for K⁺ over Na⁺ decreases and the selectivity for Ca²⁺ increases. (Adapted from Zagotta, W. N., 2006. Permutations of permeability. *Nature* 440:427–428.)

Figure 9.45 Structure of the channel from *Bacillus cereus* (PDB id = 2AHY), which has equal preference for Na⁺ and K⁺. (a) One subunit of the tetramer has been removed to reveal the five ion binding sites in the center of the channel. A Ca²⁺ ion is bound at the extracellular entrance to the channel (*aqua*, top), and K⁺ is bound to the other four sites. (b) The tetrameric channel, as viewed through the pore. (c) Substitution of D for Y in the selectivity filter eliminates binding sites 1 and 2, leaving a pore vestibule that binds a K⁺ with low affinity. Sites 3 and 4 are preserved, but bind Na⁺ and K⁺ equally well. The bottom site contains a fully hydrated K⁺, in a manner similar to the KcsA channel (Figure 9.40).

Figure 9.43 Model for voltage-dependent gating in mammalian K⁺ channels. See PDB id = 1J4C. Parts (a) and (b) show a single subunit of the channel; (c) and (d) show the native tetrameric channel. Parts (a) and (c) represent the open channel conformation; (b) and (d) show the closed state. Photo courtesy of Roderick MacKinnon.

sequence are found in ion channels with a range of selectivities for K⁺, Na⁺, and even Ca²⁺. *Bacillus cereus* contains an ion channel with equal preference for Na⁺ and K⁺ that is similar to the **transient receptor potential (TRP)** channels found widely in eukaryotes. The structure of this channel (Figure 9.45) is similar in many ways to the K⁺ channels, but the selectivity filter sequence of this **NaK channel** is TVGDG. The substitution of D for Y changes the filter in several ways. Binding sites 1 and 2, the sites most selective for K⁺, are eliminated, leaving a *pore vestibule* that can accommodate an ion but not bind it tightly. The remaining sites, binding sites 3 and 4, bind Na⁺ and K⁺ equally well. In addition, the D for Y substitution creates a Ca²⁺-binding site at the extracellular entrance to the selectivity filter (see Figure 9.45c). It appears likely that variations of the selectivity filter sequence can tune it to accommodate and select for a variety of transported cations (Figure 9.45).

9.7c CorA Is a Pentameric Mg²⁺ Channel

The transport of Mg²⁺ in bacteria and archaea is accomplished primarily by the **CorA** family of membrane channels. Its pentameric structure (Figure 9.46) contrasts with the tetrameric K⁺ and NaK channels in several ways. With a large N-terminal cytosolic domain and C-terminal transmembrane domain, it resembles a funnel or cone. One of the two transmembrane α -helices extends 100 Å into the cytosol and is the longest continuous α -helix in any known protein. Remarkable features of the structure include

Figure 9.46 The structure of the pentameric CorA Mg^{2+} channel from *Thermus maritima* (PDB id = 2HN2). The transmembrane pore is formed from five short α -helices (red) and stabilized by four longer α -helices (aqua). The pore entrance from the periplasm is gated closed by a ring of five Asn residues (gold), and a ring of five Leu (orange) and five Met (beige) residues narrows the pore to 2.5 Å. The large cytosolic domain includes a basic sphincter of 20 Lys residues (blue), and a ring of 50 Asp and Glu residues (green) at the tips of the helices. Asp⁸⁹ and Asp²⁵³ (purple) participate in Mg^{2+} binding.

a ring of 20 lysine residues around the outside of the structure near the negatively charged membrane–cytosol interface and a cluster of 50 aspartate and glutamate residues (on helices) adjacent to the lysines and extending into the cytosol. The available structures of CorA are closed-pore structures. A ring of five Asn³¹⁴ residues blocks the opening to the pore on the periplasmic face, a ring of Met²⁹¹ residues narrows the pore to 3.3 Å at the center of the membrane, and a ring of Leu²⁹⁴ residues reduce the pore diameter to 2.5 Å at the cytosolic face of the membrane. Gating of the pore must overcome these obstacles as well as the repulsive ring of positive Lys side chains. It has been hypothesized that the long α -helix and the negatively charged helices could act as a lever to pry apart the repulsive ring of lysines and open the Mg^{2+} pore.

9.7d Chloride, Water, Glycerol, and Ammonia Flow through Single-Subunit Pores

Membrane channels can also be formed within a single subunit of a protein. The **CIC channels** (which transport chloride ions and are ubiquitous in cells from bacteria to animals) are homodimeric, with each subunit having two similar halves, with opposite orientation in the membrane. The CIC pore is hourglass shaped, with a 15 Å selectivity filter in the middle (Figure 9.47a). The filter contains three Cl^- -binding sites, with coordination from Tyr and Ser hydroxyls and several peptide backbone NH groups. The Cl^- binding site nearest the extracellular solution can be occupied either by a Cl^- ion or by a glutamate carboxyl group. With the glutamate carboxyl in place, the pore is closed, but an increase in Cl^- concentration can displace the Glu side chain, with Cl^- binding to this position and opening the pore. Thus, this Cl^- channel is chloride gated.

Channel proteins often solve chemical and thermodynamic problems in innovative ways. Ion selectivity, for example, requires that ions be dehydrated in the channel, and dehydration is energetically expensive. Binding sites have to compensate for the energetic cost of dehydration by providing favorable compensatory interactions between the ion and the binding amino acid residues. The ammonia transport channel solves a

Figure 9.47 Structures of channels for (a) chloride, (b) ammonia, and (c) glycerol. All structures are axial views. (a) The CIC chloride channel from *E. coli* (PDB id = 1OTS). (b) The AmtB ammonia channel from *E. coli* with four bound NH_4^+ (PDB id = 1U7G). (c) The GlpF glycerol channel from *E. coli*, with bound glycerol (PDB id = 1FX8).

different problem. Ammonia is a gas, but the protonated ammonium ion, NH_4^+ , is the species that diffuses to the channel opening. The transport channel in this case is a hydrophobic pore 20 Å in length (Figure 9.47b). The hydrophobic character of the channel lowers the $\text{p}K_a$ of ammonium from its normal 9.25 to less than 6, facilitating the transport of NH_3 but not the monovalent cation, NH_4^+ . In the narrow hydrophobic channel, His¹⁶⁸ and His³¹⁸ line the pore and stabilize three NH_3 molecules through hydrogen bonding. On either side of the narrow pore, broad vestibules contain NH_3 in equilibrium with NH_4^+ .

Another example of selectivity for the transported species is the tetrameric glycerol channel GlpF from *E. coli*, with a transport pore in each monomer. Six transmembrane helices and two half-membrane-spanning helices form a right-handed helical bundle around each channel (Figure 9.47c). Glycerol molecules taken up by an *E. coli* cell first enter a 15 Å vestibule in the transport protein, becoming progressively dehydrated before entry into a 28 Å amphipathic channel and selectivity filter. The channel accommodates three glycerol molecules, lined up in a single file, with their alkyl backbones wedged against a hydrophobic corner and their hydroxyl groups forming hydrogen bonds with the side chains of channel residues.

The aquaporin water channels are closely related to the GlpF glycerol channel, with tetrameric structures and similar right-handed helical bundles forming transport channels. Selection for water or glycerol in these proteins is based on subtle differences in the selectivity filters within the transport channels. For example, the Phe and Trp residues that comprise the hydrophobic corner surrounding the alkyl moiety of the middle glycerol site in GlpF are replaced by a His residue in the corresponding water-binding site in aquaporin Aqp1.

9.8 How Does Energy Input Drive Active Transport Processes?

Passive and facilitated diffusion systems are relatively simple, in the sense that the transported species flow downhill energetically, that is, from high concentration to low concentration. However, other transport processes in biological systems must be *driven* in an energetic sense. In these cases, the transported species move from low concentration to high concentration, and thus the transport requires *energy input*. As such, it is considered **active transport**. The most common energy input is **ATP hydrolysis**, with hydrolysis being *tightly coupled* to the transport event. Other energy sources also drive active transport processes, including *light energy* and the *energy stored in ion gradients*. The original ion gradient is said to arise from a **primary active transport** process, and the transport that depends on the ion gradient for its energy input is referred to as a **secondary active transport** process (see later discussion of the *E. coli* proton–drug exchanger). When transport results in a net movement of electric charge across the membrane, it is referred to as **electrogenic transport**. If no net movement of charge occurs during transport, the process is electrically neutral.

9.8a All Active Transport Systems Are Energy-Coupling Devices

Hydrolysis of ATP is essentially a chemical process, whereas movement of species across a membrane is a mechanical process (that is, movement). An active transport process that depends on ATP hydrolysis thus couples chemical free energy to mechanical (translational) free energy. The bacteriorhodopsin protein in *H. halobium* couples light energy and mechanical energy. Oxidative phosphorylation involves coupling between electron transport, proton translocation, and the capture of chemical energy in the form of ATP synthesis. Similarly, the overall process of photosynthesis amounts to a coupling between captured light energy, proton translocation, and chemical energy stored in ATP.

9.8b Many Active Transport Processes Are Driven by ATP

Active transport processes use the energy of hydrolysis of ATP to drive the transport of ions, sugars, and amino acids. This section describes some of those processes.

Monovalent Cation Transport: Na^+, K^+ -ATPase All animal cells actively extrude Na^+ ions and accumulate K^+ ions. These two transport processes are driven by Na^+, K^+ -ATPase, also known as the **sodium pump**, an integral protein of the plasma membrane. Most animal cells maintain cytosolic concentrations of Na^+ and K^+ of 10 mM and 100 mM, respectively. The extracellular milieu typically contains about 100 mM to 140 mM Na^+ and 5 mM to 10 mM K^+ . Potassium is required within the cell to activate a variety of processes, whereas high intracellular sodium concentrations are inhibitory. The transmembrane gradients of Na^+ and K^+ and the resulting gradients of Cl^- and other ions provide the means by which neurons communicate. They also serve to regulate cellular volume and shape. Animal cells also depend upon these Na^+ and K^+ gradients to drive transport processes involving amino acids, sugars, nucleotides, and other substances. In fact, maintenance of these Na^+ and K^+ gradients consumes large amounts of energy in animal cells—20% to 40% of total metabolic energy in many cases and up to 70% in neural tissue.

The Na^+ - and K^+ -dependent ATPase comprises three subunits: an α -subunit of 1016 residues (120 kDa), a 35 kDa β -subunit, and a 6.5 kDa γ -subunit. The sodium pump actively pumps three Na^+ ions out of the cell and two K^+ ions into the cell per ATP hydrolyzed:

ATP hydrolysis occurs on the cytoplasmic side of the membrane (Figure 9.48), and the net movement of one positive charge outward per cycle makes the sodium pump electrogenic in nature.

Figure 9.48 The structure of the Na^+, K^+ -ATPase (a) A schematic diagram of the Na^+, K^+ -ATPase of the mammalian plasma membrane. ATP hydrolysis occurs on the cytoplasmic side of the membrane, Na^+ ions are transported out of the cell, and K^+ ions are transported in. The transport stoichiometry is three Na^+ out and two K^+ in per ATP hydrolyzed. Ouabain and other cardiac glycosides inhibit Na^+, K^+ -ATPase by binding on the extracellular surface of the pump protein. (b) Structure of the Na^+, K^+ -ATPase, showing the α -subunit, residues 28–73 of the β -subunit (gray) and the transmembrane helix (residues 23–51, yellow) of the γ -subunit (PDB id = 3N23). Ouabain and $\text{Asp}^{369}\text{-P}$ are shown as space-filling spheres.

The α -subunit of Na^+, K^+ -ATPase consists of 10 transmembrane α -helices, with three cytoplasmic domains, denoted A, P, and N. A large cytoplasmic loop between transmembrane helices four and five forms the P (phosphorylation) and N (nucleotide-binding) domains. The crystal structure of the enzyme reveals the inhibitor ouabain bound on the extracellular surface of the protein (Figure 9.48).

A minimal mechanism for Na^+, K^+ -ATPase postulates that the enzyme cycles between two principal conformations, denoted E_1 and E_2 (Figure 9.49). E_1 has a high affinity for Na^+ and ATP and is rapidly phosphorylated at Asp^{369} during ATP hydrolysis in the presence of Mg^{2+} to form $\text{E}_1\text{-P}$, a state that *contains three occluded Na^+ ions* (occluded in the sense that they are tightly bound and not easily dissociated from the enzyme in this conformation). A conformation change yields $\text{E}_2\text{-P}$, a form of the enzyme with relatively low affinity for Na^+ but a high affinity for K^+ . This state releases three Na^+ ions and binds two K^+ ions on the outside of the cell. Dephosphorylation leaves E_2K_2 , a form of the enzyme with *two occluded K^+ ions*. A conformation change, which appears to be accelerated by the binding of ATP (with a relatively low affinity), releases the bound K^+ inside the cell and returns the enzyme to the E_1 state. Enzyme forms with occluded cations represent states of the enzyme with cations bound in the transport channel. The alternation between high and low affinities for Na^+ , K^+ , and ATP serves to tightly couple the hydrolysis of ATP and ion binding and transport.

Na^+, K^+ -ATPase Is Inhibited by Cardiotonic Steroids Certain plant and animal steroids such as *ouabain* (Figure 9.50) specifically inhibit Na^+, K^+ -ATPase and ion transport. These substances are traditionally referred to as **cardiac glycosides** or **cardiotonic steroids**, both names derived from the potent effects of these molecules on the heart.

Figure 9.49 A mechanism for Na^+, K^+ -ATPase. **(a)** The model assumes two principal conformations, E_1 and E_2 . Binding of Na^+ ions to E_1 is followed by phosphorylation and release of ADP. Na^+ ions are transported and released, and K^+ ions are bound before dephosphorylation of the enzyme. Transport and release of K^+ ions complete the cycle. **(b)** The structure of the E-P intermediate formed in P-type ATPases. Residue Asp^{369} in the sodium pump attacks the γ -P of 5'-ATP to form an aspartyl phosphate (more appropriately described as a phosphoryl aspartate) in the mechanism of the Na^+, K^+ -ATPase.

Figure 9.50 The structures of several cardiotonic steroids. The lactone rings are yellow.

These molecules all possess a *cis*-configuration of the C-D ring junction, an unsaturated lactone ring (five or six membered) in the β -configuration at C-17, and a β -OH at C-14. There may be one or more sugar residues at C-3. The sugars are not required for inhibition, but do contribute to water solubility of the molecule. Cardiotonic steroids bind exclusively to the extracellular surface of Na^+, K^+ -ATPase when it is in the $\text{E}_2\text{-P}$ state, forming a very stable $\text{E}_2\text{-P}$ (cardiotonic steroid) complex.

Medical researchers studying high blood pressure have consistently found that people with hypertension have high blood levels of an endogenous Na^+, K^+ -ATPase inhibitor. In such patients, inhibition of the sodium pump in the cells lining the blood vessel wall results in accumulation of sodium and calcium in these cells and the narrowing of the vessels to create hypertension. An 8-year study aimed at the isolation and identification of the agent responsible for these effects by researchers at the University of Maryland Medical School and the Upjohn Laboratories in Michigan yielded a surprising result. Mass spectrometric analysis of compounds isolated from many hundreds of gallons of blood plasma has revealed that the hypertensive agent is ouabain itself! About half of patients with hypertension have elevated levels of endogenous ouabain (EO), even with normal salt intake, and short-term periods of high dietary salt raise EO in these individuals. On the other hand, normal individuals suppress the high EO transient triggered by high-salt diets and avoid hypertension. Elevated EO and hypertension are related to poor modulation of EO biosynthesis (mainly in the adrenal glands), altered clearance from the blood, or both.

Calcium Transport: Ca^{2+} -ATPase Calcium, an ion acting as a cellular signal in virtually all cells, plays a special role in muscles. It is the signal that stimulates muscles to contract. In the resting state, the levels of Ca^{2+} near the muscle fibers are very low (approximately $0.1 \mu\text{M}$), and nearly all of the calcium ion in muscles is sequestered inside a complex network of vesicles called the *sarcoplasmic reticulum*, or *SR*. Nerve impulses induce the SR membrane to quickly release large amounts of Ca^{2+} , with cytosolic levels rising to approximately $10 \mu\text{M}$. At these levels, Ca^{2+} stimulates contraction. Relaxation of the muscle requires that cytosolic Ca^{2+} levels be reduced to their resting values. This is accomplished by an ATP-driven Ca^{2+} transport protein known as the **Ca^{2+} -ATPase**, which bears many similarities to the Na^+, K^+ -ATPase. It has an α -subunit of the same approximate size, it forms a covalent E-P intermediate (at Asp^{351}) during ATP hydrolysis, and its mechanism of ATP hydrolysis and ion transport is similar in many ways to that of the sodium pump.

The structure of the Ca^{2+} -ATPase includes a transmembrane (M) domain consisting of 10 α -helical segments and a large cytoplasmic domain that itself consists of a nucleotide-binding (N) domain, a phosphorylation (P) domain, and an actuator (A) domain (Figure 9.51).

The calcium transport cycle begins with binding of two Ca^{2+} ions. Subsequent ATP binding causes a 90° rotation of N and a 30° rotation of A, thus joining all three cytoplasmic domains (N, A, and P), and pulling a transmembrane helix partly out of the membrane. Phosphorylation of Asp^{351} , dissociation of ADP, and conversion of the $\text{E}_1\text{-P}$ state to $\text{E}_2\text{-P}$ induce a 110° rotation of A and a rearrangement of the transmembrane domain, which acts like a piston to release Ca^{2+} inside the SR. A TGES sequence in A (residues 181 to 184) then guides nucleophilic attack of water on $\text{E}_2\text{-P}$, releasing phosphate and restoring the original structures of both the transmembrane and the cytoplasmic domains of the enzyme.

The Gastric H^+, K^+ -ATPase Production of protons is a fundamental activity of cellular metabolism, and proton production plays a special role in the stomach. The highly acidic environment of the stomach is essential for the digestion of food in all animals. The pH of the stomach fluid is normally 0.8 to 1. The pH of the parietal cells of the gastric mucosa in mammals is approximately 7.4. This represents a **pH gradient** across the mucosal cell membrane of 6.6, the largest known transmembrane gradient in eukaryotic cells. This enormous gradient must be maintained constantly so that food can be digested in the stomach without damage to

Figure 9.51 The transport cycle of the sarcoplasmic reticulum Ca^{2+} -ATPase involves at least five different conformations of the protein. The states shown here are $\text{E}_1 \cdot 2\text{Ca}^{2+}$ (PDB id = 3B9B); $\text{E}_1 \cdot \text{ATP} \cdot 2\text{Ca}^{2+}$ (PDB id = 1SU4); $\text{E}_1\text{-P} \cdot \text{ADP} \cdot 2\text{Ca}^{2+}$ (PDB id = 1T5C); $\text{E}_2 \cdot \text{P}_i$ (PDB id = 2ZBD); and E_2 (PDB id = 2EAR). Blue-shaded states in the reaction sequence correspond to adjacent structures.

the cells and organs adjacent to the stomach. The gradient of H^+ is maintained by an H^+, K^+ -ATPase, which uses the energy of hydrolysis of ATP to pump H^+ out of the mucosal cells and into the stomach interior in exchange for K^+ ions. This transport is electrically neutral, and the K^+ that is transported into the mucosal cell is subsequently pumped back out of the cell together with Cl^- in a second

A Deeper Look

Cardiac Glycosides: Potent Drugs from Ancient Times

The cardiac glycosides have a long and colorful history. Many species of plants producing these agents grow in tropical regions and have been used by South American and African indigenous groups to prepare poisoned arrows used in fighting and hunting. Zulus in South Africa, for example, have used spears tipped with cardiac glycoside poisons. The sea onion, found commonly in southern Europe and northern Africa, was used by the Romans and the Egyptians as a cardiac stimulant, diuretic, and expectorant. The Chinese have long used a medicine made from the skins of certain toads for similar purposes. Cardiac glycosides are also found in several species of domestic plants, including the foxglove, lily of the valley, oleander (figure, part a), and milkweed plants. Monarch butterflies (figure, part b) acquire these compounds by feeding on milkweed and then storing the cardiac glycosides in their exoskeletons. Cardiac glycosides deter predation of monarch butterflies by birds, which learn by experience not to feed on monarchs.

In 1785, the physician and botanist William Withering described the medicinal uses for agents derived from the foxglove plant. In modern times, **digitalis** (a preparation of dried leaves prepared from the foxglove, *Digitalis purpurea*) and other purified cardiotonic steroids have been used to increase the contractile force of heart muscle, to slow the rate of beating, and to restore normal function in hearts undergoing fibrillation (a condition in which heart valves do not open and close rhythmically but rather remain partially open, fluttering in an irregular and ineffective way). Inhibition of the cardiac sodium pump increases the intracellular Na^+ concentration, leading to stimulation of the Na^+ - Ca^{2+} exchanger, which extrudes sodium in exchange for inward movement of calcium. Increased intracellular Ca^{2+} stimulates muscle contraction. Careful use of digitalis drugs has substantial therapeutic benefit for patients with heart problems.

(a) Oleander

(a) Cardiac glycoside inhibitors of Na^+ , K^+ -ATPase are produced by many plants, including foxglove, lily of the valley, milkweed, and oleander (shown here). (b) The monarch butterfly avoids predation by birds by concentrating cardiac glycosides in its exoskeleton.

(b) Monarch butterfly

electroneutral process (Figure 9.52). Thus, the net transport effected by these two systems is the movement of HCl into the interior of the stomach. (Only a small amount of K^+ is needed because it is recycled.) The H^+ , K^+ -ATPase bears many similarities to the plasma membrane Na^+ , K^+ -ATPase and the SR Ca^{2+} -ATPase described earlier. It has a similar molecular weight, it forms an E-P intermediate (Asp^{385}), and many parts of its peptide sequence are homologous with the Na^+ , K^+ -ATPase and Ca^{2+} -ATPase.

Bone Remodeling by Osteoclast Proton Pumps Other proton-translocating ATPases exist in eukaryotic and prokaryotic systems. **Vacuolar proton-transporting ATPases** (V-type ATPases) are found in vacuoles, lysosomes, endosomes, Golgi, chromaffin granules, and coated vesicles. Various H^+ -transporting ATPases occur in yeast and bacteria as well. H^+ -transporting ATPases found in **osteoclasts** (multinucleate cells that break down bone during normal bone remodeling) provide a source of circulating calcium for soft tissues such as nerves and muscles. About 5% of bone mass in the human body undergoes remodeling at any given time. Once growth is complete, the body balances formation of new bone tissue by cells called **osteoblasts** with resorption of existing bone matrix by osteoclasts. Osteoclasts possess proton pumps—which are in fact V-type ATPases—on the portion of the plasma membrane that attaches to the bone. This region of the osteoclast membrane is called the ruffled

Figure 9.52 The H⁺,K⁺-ATPase of gastric mucosal cells mediates proton transport into the stomach. **(a)** Potassium ions are recycled by means of an associated K⁺/Cl⁻ cotransport system. The action of these two pumps results in net transport of H⁺ and Cl⁻ into the stomach. **(b)** Structure of the gastric H⁺,K⁺-ATPase, showing the phosphorylation site (Asp³⁸⁵) and the A, N, and P domains of the α-subunit. The β-subunit is gray. (PDB id = 5YLU). **(c)** The proton-binding ability (i.e., the pK_a) of the Glu⁸²⁰ carboxyl group is lowered substantially because of the close approach of Glu⁷⁹⁵, the H bond to Asn⁷⁹², and a salt bridge with Lys⁷⁹¹, enabling proton release, even at pH 1 in the gastric lumen.

Figure 9.53 Proton pumps cluster on the ruffled border of osteoclast cells and function to pump protons into the space between the cell membrane and the bone surface. High proton concentration in this space dissolves the mineral matrix of the bone.

border. The osteoclast attaches to the bone in the manner of a cup turned upside down on a saucer (Figure 9.53), leaving an extracellular space between the bone surface and the cell. The H⁺-ATPases in the ruffled border pump protons into this space, creating an acidic solution that dissolves the bone mineral matrix. Bone mineral consists mainly of poorly crystalline hydroxyapatite [Ca₁₀(PO₄)₆(OH)₂] with some carbonate (HCO₃⁻) replacing OH⁻ or PO₄³⁻ in the crystal lattice. Transport of protons out of the osteoclasts lowers the pH of the extracellular space near the bone to about 4, dissolving the hydroxyapatite.

9.8c ABC Transporters Use ATP to Drive Import and Export Functions and Provide Multidrug Resistance

The word *cell* is from the Latin *cella*, meaning a “small room.” These small rooms are kept neat and tidy by special membrane transporters known as **multidrug resistance (MDR)** efflux pumps, often referred to as molecular vacuum cleaners. MDR pumps export cellular waste molecules and toxins as well as drugs that find their way into cells in various ways. Bacteria also have influx pumps, which bring essential nutrients (for example vitamin B₁₂) into the cell (Figure 9.54). At least five families of influx and efflux pumps are known, among them the **ABC transporters**. In eukaryotes, ABC transporters are problematic because they export potentially therapeutic drugs (Figure 9.55) from cancer cells, so chemotherapy regimens must be changed often to avoid rejection of the beneficial drugs.

All ABC transporters consist of two transmembrane domains (TMDs), which form the transport pore, and two cytosolic nucleotide-binding domains (NBDs) that bind and hydrolyze ATP. The TMDs and NBDs are separate subunits (thus composing a tetramer) in bacterial ABC **importers** (Figure 9.56). Bacterial **exporters**, on the other hand, are homodimers, with each monomer made up of an N-terminal TMD and a C-terminal NBD. Eukaryotic ABC exporters are monomeric, with all four necessary domains in a single polypeptide chain.

Figure 9.54 Influx pumps in the inner membrane of gram-negative bacteria bring nutrients into the cell, whereas efflux pumps export cellular waste products and toxins. (Adapted from Garmory, H. S., and Titball, R. W., 2004. ATP-binding cassette transporters are targets for the development of antibacterial vaccines and therapies. *Infection and Immunity* 72:6757–6763.)

Figure 9.55 Some of the cytotoxic cancer drugs that are transported by the MDR ATPase.

The NBDs of ABC transporters from nearly all sources are similar in size, sequence, and structure. The TMDs, on the other hand, vary considerably in sequence, architecture, and number of transmembrane helices. ABC exporters contain a conserved core of 12 transmembrane helices, whereas ABC importers can have between 10 and 20 transmembrane helices. A variety of studies show that human MDR ATPases are similar to Sav1866, an exporting ABC transporter from *S. aureus*, and Sav1866 is considered to be a good model for the architecture of all ABC exporters.

Figure 9.56 Several ABC transporters are shown in different stages of their transport cycles. Left to right: PDB id = 1L7V, PDB id = 2QI9, PDB id = 2NQ2. **(a)** MBP is a multidrug binding protein, which binds molecules to be transported and delivers them to the transport channel. **(b)** MBP has bound to the transport channel in the middle structure and delivered the transported entity to the channel. **(c)** Transport is complete.

The structures of several ABC transporters, in different stages of the transport cycle, provide a picture of how ATP binding and hydrolysis by the NBDs might be coupled to import and export of molecules (Figure 9.56). The TMDs can cycle from inward-facing to outward-facing conformations and back again, whereas the NBDs alternate between open and closed states. In all ABC transporters, a short “coupling helix” lies at the interface between each NBD and its corresponding TMD. Binding of ATP induces closing, or joining of the NBD domains, bringing the coupling helices 10 Å to 15 Å closer to each other than in the ATP-free state. The merger of the coupling helices in turn triggers a flip-flop of the TMDs from the inward-facing to the outward-facing conformation. In this state, ABC exporters release bound drugs to the extracellular environment, whereas ABC importers accept substrate molecules from their associated substrate-binding proteins. Following ATP hydrolysis, release of ADP and inorganic phosphate allows the TMD to revert to its inward-facing conformation, where importers can release their substrates into the cytosol and exporters can bind new substrates to be exported.

9.9 How Are Certain Transport Processes Driven by Light Energy?

As noted previously, certain biological transport processes are driven by light energy rather than by ATP. Two well-characterized systems are **bacteriorhodopsin**, the light-driven H^+ -pump, and **halorhodopsin**, the light-driven Cl^- pump, of *H. halobium*, an archaeon that thrives in high-salt media. *H. halobium* grows optimally at a NaCl concentration of 4.3 M. It was extensively characterized by Walther Stoeckenius, who found it growing prolifically in the salt pools near San Francisco Bay, where salt

is commercially extracted from seawater. *H. halobium* carries out normal respiration if oxygen and metabolic energy sources are plentiful. However, when these substrates are lacking, *H. halobium* survives by using bacteriorhodopsin to capture light energy. In oxygen- and nutrient-deficient conditions, **purple patches** appear on the surface of *H. halobium*. These purple patches of membrane are comprised of 75% protein—specifically **bacteriorhodopsin (bR)**. The purple color arises from a retinal molecule that is covalently bound in a Schiff base linkage with an ϵ -NH₂ group of Lys²¹⁶ on each bacteriorhodopsin protein (Figure 9.57). Bacteriorhodopsin is a 26 kDa transmembrane protein that packs so densely in the membrane that it naturally forms a two-dimensional crystal in the plane of the membrane. The retinal moiety lies parallel to the membrane plane, about 1 nm below the membrane's outer surface (Figure 9.13).

Light energy drives transport of protons (H⁺) through bacteriorhodopsin, providing energy for the bacterium in the form of a transmembrane proton gradient. Protons hop from site to site across bacteriorhodopsin, just as a person crossing a creek would jump from one stepping stone to another. The stepping stones in bacteriorhodopsin are the carboxyl groups of Asp⁹⁶, Asp⁸⁵, Glu²⁰⁴, Glu¹⁹⁴, and the Schiff base nitrogen of the retinal chromophore (Figure 9.58). The numbered sequence of these steps (Figure 9.58) involves dramatic changes in pK_a values for the stepping stone groups, driven by conformation changes in the protein itself. In Step 1, the pK_a of the Schiff base nitrogen drops from 13.5 to about 8.5, enabling this group to donate a proton to Asp⁸⁵, whose pK_a value increases from 2.2 to more than 11, enabling it to accept the proton from the Schiff base. Similarly, the pK_a of Asp⁹⁶ is above 10 at the start of the cycle, ensuring that it will be protonated, but in Step 3, this pK_a decreases to less than 7, enabling it to donate a proton to the Schiff base, whose pK_a has returned to its high value above 13. Thus, light-induced protein conformation changes drive changes in protonation state of the stepping stone groups, facilitating proton transport across the membrane and out of the cell.

Figure 9.57 The Schiff base linkage between the retinal chromophore and Lys²¹⁶.

Figure 9.58 The mechanism of proton transport by bacteriorhodopsin, showing the locations of key residues along the proton-translocation channel and the steps of the transport process. Step 1: A proton is transferred from the retinal Schiff base to Asp⁸⁵; Step 2: A proton is released to the extracellular space from the proton release group consisting of Glu¹⁹⁴, Glu²⁰⁴, and a water molecule; Step 3: Asp⁹⁶ donates a proton to reprotonate the retinal Schiff base; Step 4: A proton is taken up from the cytoplasm by Asp⁹⁶, causing the all-*trans* retinal to be isomerized to the 13-*cis* configuration—the structural change that drives the subsequent steps; Step 5: Proton transfer from Asp⁸⁵ converts the 13-*cis* retinal back to the all-*trans* resting state (PDB id = 1M0M).

Figure 9.59 A tripartite (three-part) complex of proteins comprises the large structure in *E. coli* that exports waste and toxin molecules. The transport pump is AcrB, embedded in the bacterial inner membrane. The rest of the channel is composed of TolC, embedded in the bacterial outer membrane, and a ring of AcrA subunits, which links AcrB and TolC. (Adapted from Lomovskaya, O., Zgurskaya, H. I., et al., 2007. Waltzing transporters and ‘the dance macabre’ between humans and bacteria. *Nature Reviews Drug Discovery* 6:56–65.)

9.10 How Is Secondary Active Transport Driven by Ion Gradients?

The gradients of H^+ , Na^+ , and other cations and anions established by ATPases and other energy sources can be used for **secondary active transport** of various substrates.

9.10a Na^+ and H^+ Drive Secondary Active Transport

The best-understood secondary active transport systems use Na^+ or H^+ gradients to transport amino acids and sugars in certain cells. Many of these systems operate as **symports**, with the ion and the transported amino acid or sugar moving in the same direction (that is, into the cell). In **antiport** processes, the ion and the other transported species move in opposite directions. (For example, the anion transporter of erythrocytes is an antiport.) **Proton symport** proteins are used by *E. coli* and other bacteria to accumulate lactose, arabinose, ribose, and a variety of amino acids. *E. coli* also possesses Na^+ -symport systems for melibiose as well as for glutamate and other amino acids.

9.10b AcrB Is a Secondary Active Transport System

The ABC transporters described in Section 9.8 are just one of five different families of multidrug resistance transporters. **AcrB**, the major MDR transporter in *E. coli*, is responsible for pumping a variety of molecules including drugs such as erythromycin, tetracycline, and the β -lactams (for example, penicillin). AcrB is part of a large *tripartite complex* that bridges the *E. coli* inner and outer membranes and spans the entire periplasmic space (Figure 9.59). AcrB works with its partners, **AcrA** and **TolC**, to transport drugs and other toxins from the cytoplasm across the entire cell envelope and into the extracellular medium.

AcrB is a secondary active transport system and an **H^+ -drug antiporter**. As protons flow spontaneously inward through AcrB in the *E. coli* inner membrane, drug molecules

Figure 9.60 In the AcrB trimer, the three identical subunits adopt three different conformations. The “loose” L state (blue), the “tight” T state (yellow), and the “open” O (dusty rose) state are indicated. Possible transport paths of drugs through the tunnels are shown in green. Tunnel 1 is lined with hydrophobic residues and is the likely point of entrance for drugs in the membrane bilayer. Tunnel 2 may serve either as an entrance port for water-soluble drugs or as an exit channel for nonsubstrates. Tunnel 3 is the exit pathway. Tunnels 1 and 2 converge at the hydrophobic substrate binding pocket, where minocycline (an antibiotic similar to tetracycline) is bound in a hydrophobic pocket defined by phenylalanines 136, 178, 610, 615, 617, and 628; valines 139 and 612; isoleucines 277 and 626; and tyrosine 327. (Inset—all shown in spacefill. Minocycline is shown in stick and wireframe.) Panels A and B represent one step in a L-T-O (or T-L-O) transport cycle. (Image kindly provided by Klaas Martinus Pos.)

Figure 9.61 A model for drug transport by AcrB involves three possible conformations—loose (L, blue), tight (T, green), and open (O, pink)—for each of the three identical monomer subunits of the complex. The lateral grooves in L and T indicate low affinity and high affinity binding of drugs, respectively. The circle in the O state indicates that there is no drug binding in this state. Drugs to be transported (such as acridine, shown here) bind first to the L state. A conformational change to the T state moves the drug deeper into the tunnel, and a second conformational change opens the tunnel to the opposite side of the membrane, followed by release of the drug molecule. Binding, transport, and release of H^+ drives the drug transport cycle. (Adapted from Seeger, M., Schiefner, A., et al., 2006. Structural asymmetry of AcrB trimer suggests a peristaltic pump mechanism. *Science* **313**:1295–1298; and Eicher, T., Seeger, M. A., Anselmi, C., et al., 2014. Coupling of remote alternating-access transport mechanisms for protons and substrates in the multidrug efflux pump AcrB. *eLife* **3**:e03145.)

are driven outward. AcrB is a homotrimer of large, 1100-residue subunits. Remarkably, the three identical subunits adopt slightly different conformations, denoted loose (L), tight (T), and open (O). Transported drug molecules enter AcrB through a tunnel that starts in the periplasmic space, about 15 Å above the inner membrane, and ends at the trimer center (Figure 9.60). The three conformations of the AcrB monomers are three consecutive states of a transport cycle. As each monomer cycles through the L, T, and O states, drug molecules enter the tunnel, are bound, and then are exported (Figure 9.61). This three-step rotation has been likened to a Viennese waltz, and AcrB has been dubbed a waltzing pump by Olga Lomovskaya and colleagues.

Foundational Biochemistry Things You Should Know after Reading Chapter 9.

- Lipid and protein composition of membranes varies between tissues and subcellular organelles.
- Lipids spontaneously form a variety of stable structures in water, including micelles, vesicles, and bilayers.
- The critical micelle concentration describes the concentration at which a detergent molecule begins forming micelles in water.
- The Singer-Nicolson fluid mosaic model describes the motion inherent in bilayer membranes and defines the characteristics of integral and peripheral membrane proteins.
- Integral proteins are strongly imbedded in membranes, whereas peripheral proteins are loosely imbedded and are easily removed from the membrane.
- Integral membrane proteins may be monotopic, bitopic, or polytopic.
- The cores of integral membrane proteins are dominated by α -helices and β -sheets.
- Hydropathy plots can be used to identify putative α -helical transmembrane segments in membrane proteins.
- Nonpolar amino acids are most often found in the hydrophobic core of membrane proteins.
- Polar amino acids of membrane proteins are most often found at the lipid–water interface.
- β -Barrel proteins traverse the outer membranes of gram-negative cells and mitochondria with antiparallel β -strands.
- The four classes of lipid-anchored membrane proteins include amide-linked myristoyl anchors, acyl- and thioester-linked fatty acyl anchors, thioether-linked prenyl anchors, and amide-linked glycosyl phosphatidylinositol anchors.
- Biological membranes are characterized by lateral and transverse asymmetries.
- Phosphatidylcholine and sphingomyelin are enriched in the outer leaflet of animal plasma membranes.
- Phosphatidylserine, phosphatidylethanolamine, phosphatidic acid, and phosphatidylinositol are found mainly in the inner leaflet of animal plasma membranes.
- Lipids and proteins undergo a variety of movements in membranes.
- Flippases transport phosphatidylserine and phosphatidylethanolamine from the outer leaflet to the inner leaflet of animal plasma membranes.
- Floppases transport cholesterol, phosphatidylcholine, and sphingomyelin from the inner leaflet to the outer leaflet of animal plasma membranes.
- Scramblases randomize lipids across the bilayer and degrade transverse membrane asymmetry.
- Membrane bilayer lipids form a highly-ordered gel phase (the S_o state) at low temperatures and a more disordered liquid-crystalline phase (the L_d state) at higher temperatures.

- The liquid-ordered state of bilayer lipids (L_o) is characterized by the high degree of acyl chain ordering of the S_o state but the translational disorder of the L_d state.
- Membrane domains undergo dynamic exchange of lipids and proteins.
- Fusion of vesicles with the plasma membrane in animal cells is mediated by SNARE proteins.
- Passive diffusion, facilitated diffusion, and active transport are three modes of membrane transport.
- The free energy change for membrane transport can be calculated with terms corresponding to the chemical and electrical potential differences across a membrane.
- Channel proteins carry out voltage-gated and ligand-gated facilitated diffusion for ions and small molecules.
- The amino acids lining the transport channel of channel proteins can determine the selectivity for ions and small molecules.
- The energetic driving force for active membrane transport may be ATP hydrolysis, light energy, or the energy stored in an ion gradient.
- The P-type ATPases, including the plasma membrane Na^+, K^+ -ATPase, sarcoplasmic reticulum Ca^{2+} -ATPase, and the gastric H^+, K^+ -ATPase, form covalent E-P intermediates during their transport cycle.
- ABC transporters use ATP to drive import and export functions in prokaryotic and eukaryotic cells.
- Bacteriorhodopsin uses light-induced protein conformation changes to facilitate proton transport across the plasma membrane of *Halobacterium halobium*.
- Secondary active transport systems use gradients of protons, cations, or anions established by transport ATPases to accomplish active transport of amino acids, sugars, and other entities.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Understanding the Occurrence of Natural Phospholipids** In Problem 1 (b) in Chapter 8, you were asked to draw all the possible phosphatidylserine isomers that can be formed from palmitic and linolenic acids. Which of the PS isomers are not likely to be found in biological membranes?
- Calculation of Phospholipid-to-Protein Ratios** The purple patches of the *Halobacterium halobium* membrane, which contain the protein bacteriorhodopsin, are approximately 75% protein and 25% lipid. If the protein molecular weight is 26,000 and an average phospholipid has a molecular weight of 800, calculate the phospholipid-to-protein mole ratio.
- Membrane Composition** Folk wisdom has it that pregnant women should eat an egg every day. A single egg contains 187 mg of cholesterol. Based upon what you have learned regarding the composition of cell membranes, why does this recommendation for pregnant women make good sense?
- Understanding the Densities of Membrane Components** Sucrose gradients for separation of membrane proteins must be able to separate proteins and protein-lipid complexes with a wide range of densities, typically 1.00 g/mL to 1.35 g/mL.
 - Consult reference books (such as the *CRC Handbook of Biochemistry*) and plot the density of sucrose solutions versus percent sucrose by weight (grams of sucrose per 100 grams of solution) and versus percent by volume (grams of sucrose per 100 milliliters of solution). Why is one plot linear and the other plot curved?
 - What would be a suitable range of sucrose concentrations for separation of three membrane-derived protein-lipid complexes with densities of 1.03 g/mL, 1.07 g/mL, and 1.08 g/mL?
- Understanding Diffusion of Phospholipids in Membranes** Phospholipid lateral motion in membranes is characterized by a diffusion coefficient of about $1 \times 10^{-8} \text{ cm}^2/\text{s}$. The distance traveled in two dimensions (across the membrane) in a given time is $r = (4Dt)^{1/2}$, where r is the distance traveled in centimeters, D is the diffusion coefficient, and t is the time during which diffusion occurs. Calculate the distance traveled by a phospholipid across a bilayer in 10 ms (milliseconds).
- Understanding Diffusion of Proteins in Membranes** Protein lateral motion is much slower than that of lipids because proteins are larger than lipids. Also, some membrane proteins can diffuse freely through the membrane, whereas others are bound or anchored to other protein structures in the membrane. The diffusion constant for the membrane protein fibronectin is approximately $0.7 \times 10^{-12} \text{ cm}^2/\text{s}$, whereas that for rhodopsin is about $3 \times 10^{-9} \text{ cm}^2/\text{s}$.
 - Calculate the distance traversed by each of these proteins in 10 ms.
 - What could you surmise about the interactions of these proteins with other membrane components?
- Understanding the Phase Transitions of Membrane Phospholipids** Discuss the effects on the lipid phase transition of pure dimyristoyl phosphatidylcholine vesicles of added (a) divalent cations, (b) cholesterol, (c) distearoyl phosphatidylserine, (d) dioleoyl phosphatidylcholine, and (e) integral membrane proteins.
- Determining the Free Energy of a Galactose Gradient** Calculate the free energy difference at 25°C due to a galactose gradient across a membrane, if the concentration on side 1 is 2 mM and the concentration on side 2 is 10 mM.
- Determining the Electrochemical Potential of a Sodium Ion Gradient** Consider a phospholipid vesicle containing 10 mM Na^+ ions. The vesicle is bathed in a solution that contains 52 mM Na^+ ions, and the electrical potential difference across the vesicle membrane $\Delta\psi = \psi_{\text{outside}} - \psi_{\text{inside}} = -30 \text{ mV}$. What is the electrochemical potential at 25°C for Na^+ ions?
- Digoxin** Digoxin (in Lanoxin and other formulations) is a commonly used drug. Look up the structure of digoxin and compare it to other molecules described in this chapter. Based on what you have learned in this chapter, what may be the therapeutic applications of this drug (diseases or conditions treated) and its mode of action?
- Assessing the Nature of Transmembrane Histidine Transport** Transport of histidine across a cell membrane was measured at several histidine concentrations:

[Histidine], μM	Transport, $\mu\text{mol}/\text{min}$
2.5	42.5
7	119
16	272
31	527
72	1220

Does this transport operate by passive diffusion or by facilitated diffusion?

- 12. Determining the Concentration Limits of an Active Transport System** (Integrates with Chapter 3.) Fructose is present outside a cell at $1\ \mu\text{M}$ concentration. An active transport system in the plasma membrane transports fructose into this cell, using the free energy of ATP hydrolysis to drive fructose uptake. What is the highest intracellular concentration of fructose that this transport system can generate? Assume that one fructose is transported per ATP hydrolyzed; that ATP is hydrolyzed on the intracellular surface of the membrane; and that the concentrations of ATP, ADP, and P_i are $3\ \text{mM}$, $1\ \text{mM}$, and $0.5\ \text{mM}$, respectively. $T = 298\ \text{K}$. (Hint: Refer to Chapter 3 to recall the effects of concentration on free energy of ATP hydrolysis.)
- 13. Assessing the Energy Coupling of a Transport Process** In this chapter, we have examined coupled transport systems that rely on ATP hydrolysis or on primary gradients of Na^+ or H^+ . Suppose you have just discovered an unusual strain of bacteria that transports rhamnose across its plasma membrane. Suggest experiments that would test whether it was linked to any of these other transport systems.
- 14. Characterization of a Myristoyl Lipid Anchor** Which of the following peptides would be the most likely to acquire an N-terminal myristoyl lipid anchor?
- VLIHGLEQN
 - THISISIT
 - RIGHTHERE
 - MEMEME
 - GETREAL
- 15. Characterization of a Prenyl Lipid Anchor** Which of the following peptides would be the most likely to acquire a prenyl anchor?
- RIGHTCALL
 - PICKME
 - ICANTICANT
 - AINTMEPICKA
 - None of the above
- 16. Creating and Analyzing a Hydropathy Plot Online** What would the hydropathy plot of a soluble protein look like, compared to those in Figure 9.14? Find out by creating a hydropathy plot. Go to: <https://web.expasy.org/protscale/>. Enter the UniProtKB/Swiss-Prot accession number P61823 for bovine pancreatic ribonuclease in the accession number box and type Return. Scroll to the bottom of the page and enter “1” into the N-terminal box and “150” in the C-terminal box. Then click Submit. At the bottom of the next page, after a few seconds, you should see a hydropathy plot. How does the plot for ribonuclease compare to those in Figure 9.14? You should see a large positive peak at the left side of the plot. This is the signal sequence portion of the polypeptide. You can read about signal sequences in Section 31.3.
- 17. Amino Acids in Ion Channels** Which amino acids would be most likely to be found in the interior of a cation channel? An anion channel? Explain. (Refer to Section 9.7a if needed.)
- 18. Ion Channel Selectivity and Hydration** Why could the hydration of ions make ion channels less selective?
- 19. Assessing the Nature of Proline in Transmembrane α -Helices** Proline residues are almost never found in short α -helices; nearly all transmembrane α -helices that contain proline are long ones (about 20 residues). Suggest a reason for this observation.
- 20. Analyzing the Structure of Proline-Containing α -Helices** As described in this chapter, proline introduces kinks in transmembrane α -helices. What are the molecular details of the kink, and why does it form? A good reference for this question is von Heijne, G., 1991. Proline kinks in transmembrane α -helices. *Journal of Molecular Biology* **218**:499–503. Another is Barlow, D. J., and Thornton, J. M., 1988. Helix geometry in proteins. *Journal of Molecular Biology* **201**:601–619.
- 21. Comparing Membrane Barrel Structures** Compare the porin proteins, which have transmembrane pores constructed from β -barrels, with the Wza protein, which has a transmembrane pore constructed from a ring of α -helices. How many amino acids are required to form the β -barrel of a porin? How many would be required to form the same-sized pore from α -helices?
- 22. Assessing the Structural Consequences of the Hop-Diffusion Model** The hop-diffusion model of Akihiro Kusumi suggests that lipid molecules in natural membranes diffuse within fenced areas before hopping the molecular fence to an adjacent area. Study Figure 9.30 and estimate the number of phospholipid molecules that would be found in a typical fenced area of local diffusion. For the purpose of calculations, you can assume that the surface area of a typical phospholipid is about $60\ \text{\AA}^2$.
- 23. Assessing the Energetic Consequences of Snorkeling in Membrane Proteins** What are the energetic consequences of snorkeling for a charged amino acid? Consider the lysine residue shown in Figure 9.16. If the lysine side chain was reoriented to extend into the center of the membrane, how far from the center would the positive charge of the lysine be? The total height of the peak for the lysine plot in Figure 9.15 is about $4kT$, where k is Boltzmann’s constant. If the lysine side chain in Figure 9.16 was reoriented to face the membrane center, how much would its energy increase? How does this value compare with the classical value for the average translational kinetic energy of a molecule in an ideal gas ($3/2kT$)?
- 24. Assessing the Dissociation Behavior of Aspartic Acid Residues in a Membrane** As described in the text, the pK_a values of Asp⁸⁵ and Asp⁹⁶ of bacteriorhodopsin are shifted to high values (more than 11) because of the hydrophobic environment surrounding these residues. Why is this so? What would you expect the dissociation behavior of aspartate carboxyl groups to be in a hydrophobic environment?
- 25. Assessing the Dissociation Behavior of Lysine and Arginine Residues in a Membrane** Extending the discussion from Problem 24, how would a hydrophobic environment affect the dissociation behavior of the side chains of lysine and arginine residues in a protein? Why?
- 26. Analyzing the Nature of Light-Driven Proton Transport** In the description of the mechanism of proton transport by bacteriorhodopsin, we find that light-driven conformation changes promote transmembrane proton transport. Suggest at least one reason for this behavior. In molecular terms, how could a conformation change facilitate proton transport?
- 27. Assessing How Transmembrane α -Helices Are Different.** Transmembrane α -helices have a higher content of hydrophobic amino acids and a lower content of charged and highly polar residues than α -helices in soluble proteins. These differences have consequences for the structure of these helices. Consult the following references and summarize the novel structural features of transmembrane α -helices. (Cross, T. A., Sharma, M., Yi, M., and Zhou, H.-X., 2014. Influence of solubilizing environments on membrane protein structures. *Trends in Biochemical Sciences* **36**:117–125; Page, R. C., Kim, S., and Cross, T. A., 2008. Transmembrane helix uniformity examined by spectral mapping of torsion angles. *Structure* **16**:787–797.)
- 28. Assessing the Survival of Monarch Butterflies Feeding on a Toxic Diet** How are monarch butterflies able to feed on the toxic milkweed plant and store cardiac glycosides in their exoskeleton without suffering the ill effects of this potent poison? Consult the following reference and summarize the biochemical accommodation that makes this possible. (Dobler, S., Dalla, S., Wagschal, V., and Agrawal, A. A., 2012. Community-wide convergent evolution in insect adaptation to toxic cardenolides by substitutions in the Na,K-ATPase. *Proceedings of the National Academy of Sciences, USA* **109**:13040–13045.)
- 29. Exploring the Mechanism of Lipid Transport by a Flippase** ATP-dependent flippases are closely related in their structures to ion pumps like the plasma membrane Na^+ , K^+ -ATPase and sarcoplasmic reticulum Ca^{2+} -ATPase, but they contend with a novel dilemma not shared by

the ion transport systems. Consult the following reference and summarize the structural features common to the flippases and P-type ATPases, and describe how the flippase solves the giant substrate problem. (Vestegaard, A. L., Coleman, J. A., Lemmin, T., et al., 2014. Critical roles of isoleucine-364 and adjacent residues in a hydrophobic gate control of phospholipid transport by the mammalian P4-ATPase ATP8A2. *Proceedings of the National Academy of Sciences, USA* **111**:16629–16638.)

- 30. Exploring the Conformational Transitions of an Ion Transport Enzyme** Structures of intermediate states of the sarcoplasmic reticulum Ca^{2+} -ATPase have begun to reveal the conformation changes that convert ATP hydrolysis free energy into transport of Ca^{2+} ions from the cytosol to the SR lumen. Consult the following reference and describe the details of piston movement by a critical transmembrane α -helix in the transport cycle of this ion pump. (Kanai, R., Ogawa, H., Vilsen, B., et al., 2013. Crystal structure of a Na^{+} -bound $\text{Na}^{+}, \text{K}^{+}$ -ATPase preceding the EIP state. *Nature* **502**:201–207; Möller, J. V., Olesen, C., Winther, A.-M., and Nissen, P., 2010. The sarcoplasmic Ca^{2+} -ATPase: design of a perfect chemi-osmotic pump. *Quarterly Review of Biophysics* **43**:501–566.)

- 31. Exploring Lipopolysaccharide Transport in a Gram-Negative Bacterium** Gram-negative bacteria have a cell wall which includes an outer membrane adorned with a tightly packed layer of lipopolysaccharide (LPS) molecules. How are these LPS molecules transported to the outer membrane? Consult the following references and describe the details of LPS transport and the membrane structures that are involved in this transport. (Bishop, R. E., 2014. Lipopolysaccharide rolls out the barrel. *Nature* **511**:37–38; Dong, H., Xiang, Q., Gu, Y., et al., 2014. Structural basis for outer membrane lipopolysaccharide insertion. *Nature* **511**:52–57; Qiao, S., Luo, Q., Zhao, Y., et al., 2014.

Structural basis for lipopolysaccharide insertion in the bacterial outer membrane. *Nature* **511**:108–111.)

- 32. Understanding the Fluid Mosaic Model** Singer and Nicolson's fluid mosaic model of membrane structure presumed all of the following statements to be true EXCEPT:
- The phospholipid bilayer is a fluid matrix.
 - Proteins can be anchored to the membrane by covalently linked lipid chains.
 - Proteins can move laterally across a membrane.
 - Membranes should be about 5 nm thick.
 - Transverse motion of lipid molecules can occur occasionally.

Think-Pair-Share Question

Drug Diffusion through Patches Transdermal patches are designed to deliver a steady amount of drug from the patch through the skin layers into the general circulation. The diagram shows schematically this type of drug delivery system.

The drug delivery process is driven by passive diffusion. With a fellow student, discuss as many parameters as you can think of that determine the rate of drug movement from its reservoir to the general circulation.

Nucleotides and Nucleic Acids

10

We have discovered the secret of life!

Proclamation by Francis H. C. Crick to patrons of The Eagle, a pub in Cambridge, England (1953)

A. Barrington Brown/Photo Researchers, Inc.

◀ Francis Crick (*right*) and James Watson (*left*) point out features of their model for the structure of DNA.

Essential Question

Nucleotides and nucleic acids are substances that contain nitrogen bases (aromatic cyclic groups possessing nitrogen atoms) as part of their structure. Nucleotides are essential to cellular metabolism, and nucleic acids are the molecules of genetic information storage and expression. **What are the structures of the nucleotides? How are nucleotides joined together to form nucleic acids? How is information stored in nucleic acids? What are the biological functions of nucleotides and nucleic acids?**

Nucleotides are biological molecules that possess a heterocyclic nitrogenous base, a five-carbon sugar (pentose), and phosphate as principal components of their structure. The biochemical roles of nucleotides are numerous; they participate as essential intermediates in virtually all aspects of cellular metabolism. Serving an even more central biological purpose are the **nucleic acids**, the elements of heredity and the agents of genetic information transfer. Just as proteins are linear polymers of amino acids, nucleic acids are linear polymers of nucleotides. Like the letters in this sentence, the orderly sequence of nucleotide residues in a nucleic acid can encode information. The two basic kinds of nucleic acids are **deoxyribonucleic acid (DNA)** and **ribonucleic acid (RNA)**. The five-carbon sugar in DNA is 2-deoxyribose; in RNA, it is ribose. DNA is the repository of genetic information in cells, whereas RNA serves in the expression of this information through the processes of **transcription** and **translation** (Figure 10.1). An interesting exception to this rule is that some viruses have their genetic information stored as RNA.

This chapter describes the chemistry of nucleotides and the major classes of nucleic acids. Chapter 11 presents methods for the determination of nucleic acid primary structure (nucleic acid sequencing) and describes the higher orders of nucleic acid structure. Chapter 12 introduces the *molecular biology of genetic engineering*: the construction and uses of novel DNA molecules assembled by combining segments from different DNA molecules.

Key Questions

- 10.1** What Are the Structure and Chemistry of Nitrogenous Bases?
- 10.2** What Are Nucleosides?
- 10.3** What Are the Structure and Chemistry of Nucleotides?
- 10.4** What Are Nucleic Acids?
- 10.5** What Are the Different Classes of Nucleic Acids?
- 10.6** Are Nucleic Acids Susceptible to Hydrolysis?

Figure 10.1 The fundamental process of information transfer in cells.

10.1 What Are the Structure and Chemistry of Nitrogenous Bases?

The bases of nucleotides and nucleic acids are derivatives of either **pyrimidine** or **purine**. Pyrimidines are six-membered heterocyclic aromatic rings containing two nitrogen atoms (Figure 10.2a). (In organic chemistry, **heterocyclic** ring structures contain atoms other than carbon atoms.) The atoms are numbered in a clockwise fashion, as shown in Figure 10.2. The purine ring system consists of two rings of atoms: one resembling the pyrimidine ring and another resembling the imidazole ring (Figure 10.2b). The nine atoms in this fused ring system are numbered according to the convention shown.

The pyrimidine ring system is planar, whereas the purine system deviates somewhat from planarity in having a slight pucker between its imidazole and pyrimidine portions. Both are relatively insoluble in water, as might be expected from their pronounced aromatic character.

Figure 10.2 (a) The pyrimidine ring system; by convention, atoms are numbered as indicated. (b) The purine ring system, atoms numbered as shown.

10.1a Three Pyrimidines and Two Purines Are Commonly Found in Cells

The common naturally occurring pyrimidines are **cytosine**, **uracil**, and **thymine** (5-methyluracil) (Figure 10.3). Cytosine and thymine are the pyrimidines typically found in DNA, whereas cytosine and uracil are common in RNA. Note that the 5-methyl group of thymine is the only thing that distinguishes it from uracil. Various pyrimidine derivatives, such as dihydrouracil, are present as minor constituents in certain RNA molecules.

Adenine (6-amino purine) and **guanine** (2-amino-6-oxy purine), the two common purines, are found in both DNA and RNA (Figure 10.4). Other naturally occurring

Figure 10.3 The common pyrimidine bases—cytosine, uracil, and thymine—in the tautomeric forms predominant at pH 7.

purine derivatives include **hypoxanthine**, **xanthine**, and **uric acid** (Figure 10.5). Hypoxanthine and xanthine are found only rarely as constituents of nucleic acids. Uric acid, the most oxidized state for a purine derivative, is never found in nucleic acids.

10.1b The Properties of Pyrimidines and Purines Can Be Traced to Their Electron-Rich Nature

The aromaticity of the pyrimidine and purine ring systems and the electron-rich nature of their carbonyl and ring nitrogen substituents endow them with the capacity to undergo **keto–enol tautomeric shifts**. That is, pyrimidines and purines exist as tautomeric pairs, as shown in Figure 10.6 for uracil and Figure 10.7 for guanine. **Tautomers** are chemical isomers that interconvert through the relocation of a hydrogen atom. Tautomeric pairs differ in their hydrogen-bonding possibilities, a property that is key to nucleic acid structure and function. The keto tautomers of uracil, thymine, and guanine vastly predominate at neutral pH. In other words, pK_a values for ring nitrogen atoms 1 and 3 in uracil (Figure 10.6) are greater than 8 (the pK_a value for N-3 is 9.5). In contrast, the enamine form of cytosine predominates at pH 7 and the pK_a value for N-3 in this pyrimidine is 4.5. Similarly, for guanine (Figure 10.7), the pK_a value is 9.4 for N-1 and less than 5 for N-3. These pK_a values specify whether protons are associated with the various ring nitrogens at neutral pH. As such, they are important in determining whether these nitrogens serve as H-bond donors or acceptors. Hydrogen bonding between purine and pyrimidine bases is fundamental to the biological functions of nucleic acids, as in the formation of the double-helix structure of DNA. The important functional groups participating in H-bond formation are the amino groups of cytosine, adenine, and guanine; the ring nitrogens at position 3 of pyrimidines and position 1 of purines; and the strongly electronegative oxygen atoms attached at position 4 of uracil and thymine, position 2 of cytosine, and position 6 of guanine (see Figure 10.17).

Another property of pyrimidines and purines is their strong absorbance of ultraviolet (UV) light, with wavelengths in the 260 nm region. This property is particularly useful in the quantitative and qualitative analysis of substances containing these nitrogenous bases, including nucleosides, nucleotides, and nucleic acids.

10.2 | What Are Nucleosides?

Nucleosides are compounds formed when a base is linked to a sugar. The sugars of nucleosides are **pentoses** (five-carbon sugars, see Chapter 7). **Ribonucleosides** contain the pentose D-ribose, whereas 2-deoxy-D-ribose is found in **deoxyribonucleosides**. In both instances, the pentose is in the five-membered ring form furanose: D-ribofuranose for ribonucleosides and 2-deoxy-D-ribofuranose for deoxyribonucleosides (Figure 10.8). In nucleosides, these ribofuranose atoms are numbered 1', 2', 3', and so on to distinguish them from the ring atoms of the nitrogenous bases. The base is linked to the sugar via a **glycosidic bond**. Glycosidic bonds in nucleosides (and nucleotides, see

Human Biochemistry

Adenosine: A Nucleoside with Physiological Activity

For the most part, nucleosides have no biological role other than to serve as component parts of nucleotides. Adenosine is a rare exception. In mammals, adenosine functions as an **autacoid**, or local hormone, and as a neuromodulator. This nucleoside circulates in the bloodstream, acting locally on specific cells to influence such diverse physiological phenomena as blood vessel dilation, smooth muscle contraction, neuronal discharge, neurotransmitter release, and metabolism of fat. For example, when muscles work hard, they release adenosine, causing the surrounding blood vessels to dilate, which in turn increases the flow of blood and its delivery of O_2 and nutrients to the muscles. In a different autacoid role, adenosine acts in regulating heartbeat. The natural rhythm of the heart is controlled by a pacemaker, the sinoatrial node, which cyclically sends a wave of electrical excitation to the heart muscles. By blocking the flow of electrical current, adenosine slows the heart rate. *Supraventricular tachycardia* is a heart condition characterized by a rapid heartbeat. Intravenous injection of adenosine causes a momentary interruption of the rapid cycle of contraction and restores a normal heart rate. Adenosine is licensed and marketed as *Adenocard* to treat supraventricular tachycardia.

In addition, adenosine is implicated in sleep regulation. During periods of extended wakefulness, extracellular adenosine levels rise as a result of metabolic activity in the brain, and this increase

promotes sleepiness. During sleep, adenosine levels fall. Caffeine promotes wakefulness by blocking the interaction of extracellular adenosine with its neuronal receptors.

Caffeine is an alkaloid, a term used to define naturally occurring nitrogenous molecules that have pharmacological effects. Alkaloids are classified according to their metabolic precursors, so caffeine is a purine alkaloid.

following discussion) are always of the β -configuration. Nucleosides are named by adding the ending *-idine* to the root name of a pyrimidine or *-osine* to the root name of a purine. The common nucleosides are thus **cytidine**, **uridine**, **thymidine**, **adenosine**, and **guanosine** (Figure 10.9). Nucleosides are more water soluble than the free bases because of the hydrophilicity of the pentose.

10.3 What Are the Structure and Chemistry of Nucleotides?

A **nucleotide** results when phosphoric acid is esterified to a sugar —OH group of a nucleoside. The nucleoside ribose ring has three —OH groups available for esterification, at C-2', C-3', and C-5' (although 2'-deoxyribose has only two). The vast majority of monomeric nucleotides in the cell are **ribonucleotides** with 5'-phosphate groups. Figure 10.10 shows the structures of the common four *ribonucleotides*, whose formal names are **adenosine 5'-monophosphate**, **guanosine 5'-monophosphate**, **cytidine**

Figure 10.9 The common ribonucleosides—cytidine, uridine, adenosine, and guanosine—and the less-common inosine. (Purine nucleosides and nucleotides usually adopt the anti conformation, where the purine ring is not above the ribose, as it would be in the syn conformation. Pyrimidines are always anti, never syn, because the 2-O atom of pyrimidines sterically hinders the ring from a position above the ribose.)

Figure 10.10 Structures of the four common ribonucleotides—AMP, GMP, CMP, and UMP. Also shown is the nucleotide 3'-AMP. 3'-Nucleoside monophosphates are common products of nucleic acid hydrolysis.

5'-monophosphate, and **uridine 5'-monophosphate**. These compounds are more often referred to by their abbreviations: **5'-AMP**, **5'-GMP**, **5'-CMP**, and **5'-UMP**, or even more simply as **AMP**, **GMP**, **CMP**, and **UMP**. Because the pK_a value for the first dissociation of a proton from the phosphoric acid moiety is 1.0 or less, the nucleotides have acidic properties. This acidity is implicit in the other names by which these

Figure 10.11 The cyclic nucleotides cAMP and cGMP.

substances are known—**adenylic acid**, **guanylic acid**, **cytidylic acid**, and **uridylic acid**. The pK_a value for the second dissociation, pK_2 , is about 6.0, so at neutral pH or above, the net charge on a nucleoside monophosphate is -2 . Nucleic acids, which are polymers of nucleoside monophosphates, derive their name from the acidity of these phosphate groups.

10.3a Cyclic Nucleotides Are Cyclic Phosphodiesterases

Nucleoside monophosphates in which the phosphoric acid is esterified to *two* of the available ribose hydroxyl groups (Figure 10.11) are found in all cells. Forming two such ester linkages with one phosphate results in a cyclic phosphodiester structure. **3',5'-cyclic AMP**, often abbreviated **cAMP**, and its guanine analog **3',5'-cyclic GMP**, or **cGMP**, are important regulators of cellular metabolism. The cyclic pyrimidine nucleotides, cCMP and cUMP, also occur in cells and affect many of the same processes controlled by cAMP and cGMP.

10.3b Nucleoside Diphosphates and Triphosphates Are Nucleotides with Two or Three Phosphate Groups

Additional phosphate groups can be linked to the phosphoryl group of a nucleotide through the formation of phosphoric anhydride linkages, as shown in Figure 10.12. Addition of a second phosphate to AMP creates **adenosine 5'-diphosphate**, or **ADP**, and adding a third yields **adenosine 5'-triphosphate**, or **ATP**. The respective phosphate

Human Biochemistry

cGAMP, a Cyclic Dinucleotide That Triggers a Response to Infection

Second messengers are regulatory metabolites produced in cells in response to some signal. cAMP and cGMP are the best known second messengers (Figure 10.11). The first description of **cyclic dinucleotides** as second messengers dates to 1987 when the dicyclic nucleotide bis-(3'-5')-cyclic dimeric GMP (c-di-GMP, see figure) was identified as the signal causing bacteria to switch from the free-living single-cell state into the formation of biofilms on surfaces.

When animals sense double-stranded DNA (dsDNA) in the cytosol, they produce an anti-pathogen known as type I interferon (IFN). IFNs activate the immune system, which acts to protect the organism from the infection. (dsDNA is normally found only in the cell nucleus or in mitochondria, so its presence in the cytosol is indication of an invading bacterium or a virus.) Cytosolic detection of dsDNA activates *stimulator of interferon genes* (STING), instigating a program of gene expression aimed at halting infection. The cytosolic DNA sensor is cyclic GMP-AMP synthase (cGAS), the

enzyme that synthesizes cyclic GMP-AMP (cGAMP; also known as cyclic G(2',5')pA(3',5')p; see figure) from GTP and ATP. Binding of dsDNA to cGAS causes a conformational change in the enzyme that establishes a catalytically competent nucleotide-binding site where the GTP and ATP substrates bind and cGAMP synthesis occurs. Rising [cGAMP] levels trigger STING expression and an immune response. An undesirable consequence of this system is that self-nucleic acid recognition (host dsDNA in the cytosol) may induce autoimmune diseases such as lupus erythematosus.

groups are designated by the Greek letters α , β , and γ , starting with the α -phosphate as the one linked directly to the pentose. The abbreviations **GTP**, **CTP**, and **UTP** represent the other corresponding nucleoside 5'-triphosphates. Like the nucleoside 5'-monophosphates, the nucleoside 5'-diphosphates and 5'-triphosphates all occur in the free state in the cell, as do their deoxyribonucleoside phosphate counterparts, represented as dAMP, dADP, and dATP; dGMP, dGDP, and dGTP; dCMP, dCDP, and dCTP; dUMP, dUDP, and dUTP; and dTMP, dTDP, and dTTP.

10.3c NDPs and NTPs Are Polyprotic Acids

Nucleoside 5'-diphosphates (NDPs) and **nucleoside 5'-triphosphates (NTPs)** are relatively strong *polyprotic acids* in that they dissociate three and four protons, respectively, from their phosphoric acid groups. The resulting phosphate anions on NDPs and NTPs form stable complexes with divalent cations such as Mg^{2+} and Ca^{2+} . Because Mg^{2+} is present at high concentrations (as much as 40 mM) intracellularly, NDPs and NTPs occur primarily as Mg^{2+} complexes in the cell.

10.3d Nucleoside 5'-Triphosphates Are Carriers of Chemical Energy

Nucleoside 5'-triphosphates are indispensable agents in metabolism because the phosphoric anhydride bonds they possess are a prime source of chemical energy to do biological work.

Virtually all of the biochemical reactions of nucleotides involve either *phosphoryl group transfer*, *pyrophosphoryl group transfer*, or *nucleotidyl group transfer*: the transfer of a phosphoryl, pyrophosphoryl, or NMP (nucleotidyl) group from an NTP to an acceptor (Figure 10.13). The pentose and the base are *not* directly involved in this chemistry. The base serves as a recognition symbol that allows the cell to partition its chemical energy to the different metabolic pathways: ATP to serve as the primary nucleotide in central pathways of energy metabolism, whereas GTP is used to drive protein synthesis. CTP is essential for phospholipid synthesis, and UTP forms activated intermediates with sugars that go on to serve as substrates in the biosynthesis of complex carbohydrates and polysaccharides. Thus, the various nucleotides are channeled in appropriate metabolic directions through specific recognition of the base of the nucleotide. The bases of nucleotides never participate directly in the covalent bond

chemistry that goes on. To complete the picture, the four NTPs and their dNTP counterparts are the substrates for synthesis of the remaining class of biomolecules—the nucleic acids.

10.4 | What Are Nucleic Acids?

Nucleic acids are **polynucleotides**: linear polymers of nucleotides linked 3' to 5' by **phosphodiester bridges** (Figure 10.14). Phosphodiester bridges occur when one phosphate group is esterified to two different —OH groups. Phosphodiester bridges are the fundamental linkage creating polynucleotides from nucleotide monomers. They are formed as 5'-nucleoside monophosphates units are successively added to the 3'-OH group of the preceding nucleotide, a process that gives the polymer a directional sense. Polymers of ribonucleotides are named ribonucleic acid, or RNA. Deoxyribonucleotide polymers are called deoxyribonucleic acid, or DNA. Because C-1' and C-4' in deoxyribonucleotides are involved in furanose ring formation and because there is no 2'-OH, only the 3'- and 5'-hydroxyl groups are available for internucleotide phosphodiester bonds. In the case of DNA, a polynucleotide chain may contain hundreds of millions of nucleotide units. *The convention in all notations of nucleic acid structure is to read the polynucleotide chain from the 5'-end of the polymer to the 3'-end.* Note that this reading direction actually passes through each phosphodiester from 3' to 5' (Figure 10.14). A repetitious uniformity exists in the covalent backbone of polynucleotides.

Figure 10.14 3', 5'-Phosphodiester bridges link nucleotides together to form polynucleotide chains. RNA is shown on the left and DNA on the right. The 5'-ends of the chains are at the top; the 3'-ends are at the bottom. The nucleotide sequence of the RNA would be read as ACGU; that of the DNA as TGCA

10.4a The Base Sequence of a Nucleic Acid Is Its Defining Characteristic

The only significant variation that commonly occurs in the chemical structure of nucleic acids is the nature of the base at each nucleotide position. These bases are not part of the sugar–phosphate backbone but instead serve as distinctive side chains, much like the R groups of amino acids along a polypeptide backbone. They give the polymer its unique identity. A simple notation for nucleic acid structures is merely to list the order of bases in the polynucleotide using single capital letters—A, G, C, and U (or T).

Careers in Chemistry

Philip Nega

Philip Nega received his Bachelors of Science in Chemistry from Haverford College and his Masters of Science in Engineering from University of Pennsylvania. He currently uses his education to further research in solid state battery technology for A123 Systems, a manufacturer of lithium iron phosphate batteries and energy storage systems.

Nega worked previously at Lawrence Berkeley National Lab with perovskite structures, using robotics to perform more than 100 reactions at a time. He describes his knowledge of biochemistry as essential to understanding and assessing the structural and chemical properties of the materials he has studied in his career.

Occasionally, a lowercase “p” is written between each successive base to indicate the phosphodiester bridge, as in GpApCpGpUpA.

To distinguish between RNA and DNA sequences, DNA sequences may be preceded by a lowercase “d” to denote deoxy, as in d-GACGTA. Or, one can surmise from sequences containing U, but not T, that the nucleotide sequence given is for an RNA. From a simple string of letters such as this, any biochemistry student should be able to draw the unique chemical structure of, for example, a pentanucleotide, even though it may contain more than 200 atoms.

10.5 | What Are the Different Classes of Nucleic Acids?

The two major classes of nucleic acids are DNA and RNA. DNA has only one biological role, but it is the more central one. The information to make all the functional macromolecules of the cell (even DNA itself) is preserved in DNA and accessed through transcription of the information into RNA copies. Coincident with DNA’s singular purpose, simple life forms such as viruses or bacteria usually contain only a single DNA molecule (or “chromosome”). Such DNA molecules must be quite large in order to carry enough information for making the macromolecules necessary to maintain a living cell. The *Escherichia coli* chromosome has a molecular mass of 2.9×10^9 Da and contains more than 9 million nucleotides. Eukaryotic cells have many chromosomes, and DNA is found principally in two copies in the diploid chromosomes of the nucleus. DNA is also found in mitochondria and in chloroplasts, where it encodes some of the proteins and RNAs unique to these organelles.

In contrast, RNA occurs in multiple copies and various forms. Cells typically contain about eight times as much RNA as DNA. RNA has a number of important biological functions. Its central one is information transfer from DNA to protein. RNA molecules playing this role are categorized into several major types: **messenger RNA**, **ribosomal RNA**, **transfer RNA**, and **small nuclear RNA**. Another type, **small RNAs** (RNA 21 to 28 nucleotides in length), consists of important players in gene regulation. Beyond various roles in information transfer, RNA participates in a number of metabolic functions, including the processing and modification of tRNA, rRNA, and mRNA and several maintenance or “housekeeping” functions, such as the preservation of telomeres (the special sequences at the ends of chromosomes). Furthermore, like proteins, RNA strands can fold into complex architectural arrangements that allow them to bind ligands with high specificity. Such ligand-binding specificity can even endow these RNAs with catalytic (that is, enzymatic) activity.

With these basic definitions in mind, let’s now briefly consider the chemical and structural nature of DNA and the various RNAs.

10.5a The Fundamental Structure of DNA Is a Double Helix

The DNA isolated from different cells and some viruses characteristically consist of two polynucleotide strands wound together to form a long, slender, helical molecule, the **DNA double helix**. The strands run in opposite directions; that is, they are *antiparallel*. The two strands are held together in the double-helical structure through *interchain hydrogen bonds* (Figure 10.15). These H bonds pair the bases of nucleotides in one chain to complementary bases in the other, a phenomenon called **base pairing**.

Erwin Chargaff’s Analysis of the Base Composition of Different DNAs Provided a Key Clue to DNA Structure A clue to the chemical basis of base pairing in DNA came from the analysis of the base composition of various DNAs by Erwin Chargaff in the late 1940s. His data showed that the four bases commonly found in DNA (A, C, G, and T) do not occur in equimolar amounts and that the relative amounts of each vary from

Figure 10.15 The antiparallel nature of the DNA double helix.

species to species (Table 10.1). Nevertheless, Chargaff noted that certain pairs of bases, namely, adenine and thymine, and guanine and cytosine, are always found in a 1:1 ratio and that the number of pyrimidine residues always equals the number of purine residues. These findings are known as *Chargaff's rules*: $[A] = [T]$; $[C] = [G]$; $[\text{pyrimidines}] = [\text{purines}]$.

Watson and Crick's Postulate of the DNA Double Helix Became the Icon of DNA Structure James Watson and Francis Crick, working in the Cavendish Laboratory at Cambridge University in 1953, took advantage of Chargaff's results and the data obtained by Rosalind Franklin and Maurice Wilkins in X-ray diffraction studies on the structure of DNA to conclude that DNA was a *complementary double helix*. Two strands of deoxyribonucleic acid (sometimes referred to as the *Watson strand* and the *Crick strand*) are held together by the bonding interactions between

Figure 10.16 The Watson–Crick base pairs A:T and G:C.

Figure 10.17 The replication of DNA gives identical progeny molecules because base pairing is the mechanism that determines the nucleotide sequence of each newly synthesized strand.

unique base pairs, always consisting of a purine in one strand and a pyrimidine in the other. Base pairing is very specific: If the purine is adenine, the pyrimidine must be thymine. Similarly, guanine pairs only with cytosine (Figure 10.16). Thus, if an A occurs in one strand of the helix, T must occupy the complementary position in the opposing strand. Likewise, a G in one dictates a C in the other. Because of this exclusive pairing of A only with T and G only with C, these pairs are taken as the standard or accepted law, and the A:T and G:C base pairs are often referred to as canonical. As Watson recognized from testing various combinations of bases using structurally accurate models, the A:T pair and the G:C pair form spatially equivalent units (Figure 10.16). The backbone-to-backbone distance of an A:T pair is 1.11 nm, virtually identical to the 1.08-nm chain separation in G:C base pairs.

Base pairing in the DNA molecule not only conforms to Chargaff results and Watson and Crick's rules, but also has a profound property relating to heredity: *The sequence of bases in one strand has a complementary relationship to the sequence of bases in the other strand.* That is, the information contained in the sequence of one strand is conserved in the sequence of the other. Therefore, separation of the two strands and faithful replication of each, through a process in which base pairing specifies the nucleotide sequence in the newly synthesized strand, leads to two progeny molecules identical in every respect to the parental double helix (Figure 10.17). Elucidation of the double-helical structure of DNA represented one of the most significant events in the history of science. This discovery, more than any other, marked the beginning of molecular biology. Indeed, upon solving the structure of DNA, Crick proclaimed in *The Eagle*, a pub just across from the Cavendish lab, “We have discovered the secret of life!”

The Information in DNA Is Encoded in Digital Form In this digital age, we are accustomed to electronic information encoded in the form of extremely long arrays of just two digits: ones (1s) and zeros (0s). DNA uses four digits to encode biological information: A, C, G, and T. A significant feature of the DNA double helix is that virtually any base sequence (encoded information) is possible: Other than the base-pairing rules, no structural constraints operate to limit the potential sequence of bases in DNA.

DNA contains two kinds of information:

1. The nucleotide sequences of genes that encode the amino acid sequences of proteins and the nucleotide sequences of functional RNA molecules such as rRNA and tRNA (see the following discussion).
2. The gene regulatory networks that control the expression of protein-encoding (and functional RNA-encoding) genes (see Chapter 29).

DNA Is in the Form of Enormously Long, Threadlike Molecules Because of the double helical nature of DNA molecules, their size can be represented in terms of the numbers of paired nucleotides (or **base pairs**) they contain. For example, the *E. coli* chromosome consists of 4.64×10^6 base pairs (abbreviated bp) or 4.64×10^3 kilobase pairs (kbp). DNA is a threadlike molecule. The diameter of the DNA double helix is only 2 nm, but the length of the DNA molecule forming the *E. coli* chromosome is over 1.6×10^6 nm (1.6 mm). The long dimension of an *E. coli* cell is only 2000 nm (0.002 mm), so its chromosome must be highly folded. Because of their long, threadlike nature, DNA molecules are easily sheared into shorter fragments during isolation procedures, and it is technically challenging to obtain intact chromosomes even from the simple cells of prokaryotes.

DNA in Cells Occurs in the Form of Chromosomes DNA occurs in various forms in different cells. The single chromosome of prokaryotic cells is typically a circular DNA molecule. Proteins are associated with prokaryotic DNA, but unlike eukaryotic chromosomes, prokaryotic chromosomes are not uniformly organized into ordered nucleoprotein arrays. The DNA molecules of eukaryotic cells, each of which defines a chromosome, are linear and richly adorned with proteins (Figure 10.18). A class of arginine- and lysine-rich basic proteins called **histones** interact electrostatically with the anionic phosphate groups in the DNA backbone to form **nucleosomes**, structures in which the DNA double helix is wound around a protein core composed of pairs of four different histone polypeptides. Chromosomes also contain a varying mixture of other proteins, so-called **nonhistone chromosomal proteins**, many of which are involved in regulating which genes in DNA are transcribed at any given moment. The amount of DNA in a diploid mammalian cell is typically more than 1000 times that found in an *E. coli* cell. Some higher plant cells contain more than 50,000 times as much as an *E. coli* cell.

Figure 10.18 A diagrammatic representation of a typical eukaryotic chromosome. The double-stranded DNA molecule is wound around nucleosomes composed of histone proteins, which are condensed into higher-order structural arrangements and decorated with nonhistone chromosomal proteins.

10.5b Various Forms of RNA Serve Different Roles in Cells

Unlike DNA, cellular RNA molecules are almost always single stranded. However, all of them typically contain double-stranded regions formed when stretches of nucleotides with complementary base sequences align in an antiparallel fashion and form canonical A:U and G:C base pairs. (Compare Figures 10.3 and 10.16 to convince yourself that U would pair with A in the same manner T does.) Such base pairing creates secondary structure.

Messenger RNA Carries the Sequence Information for Synthesis of a Protein Messenger RNA (mRNA) serves to carry the information, or message, encoded in genes to the sites of protein synthesis in the cell where this information is translated into a polypeptide sequence. That is, mRNA molecules are transcribed copies of the protein-coding genetic units of DNA. Prokaryotic mRNAs have from 75 to 3000 nucleotides; mRNA constitutes about 2% of total prokaryotic RNA.

Messenger RNA is synthesized during transcription, an enzymatic process in which an RNA copy is made of the sequence of bases along one strand of DNA. This mRNA then directs the synthesis of a polypeptide chain as the information that is contained within its nucleotide sequence is translated into an amino acid sequence by the protein-synthesizing machinery of the ribosomes. Ribosomal RNA and tRNA molecules are also synthesized by the transcription of DNA sequences, but unlike mRNA molecules, these RNAs are not subsequently translated to form proteins. In prokaryotes, a single mRNA may contain information for the synthesis of several polypeptide chains within its nucleotide sequence (Figure 10.19). In contrast, eukaryotic mRNAs encode only one polypeptide but are more complex—they are synthesized in the nucleus in the form of much larger precursor molecules called **heterogeneous nuclear RNA**, or **hnRNA**. hnRNA molecules contain stretches of nucleotide sequence that have no protein-coding capacity. These noncoding regions are called **intervening sequences** or **introns** because they intervene between coding regions, which are called **exons**. Introns interrupt the continuity of the information specifying the amino acid sequence of a protein and must be spliced out before the message can be translated. In addition, eukaryotic hnRNA and mRNA molecules have a run of 100 to 200 adenylic acid residues attached at their 3'-ends, so-called **poly(A) tails**. This polyadenylation occurs after transcription has been completed and is essential for efficient translation and stability of the mRNA. The properties of mRNA molecules as they move through transcription and translation in prokaryotic versus eukaryotic cells are summarized in Figure 10.19.

Ribosomal RNA Provides the Structural and Functional Foundation for Ribosomes

Ribosomes, the ribonucleoprotein complexes where protein synthesis occurs, are about 65% RNA of the ribosomal RNA type. Ribosomal RNA (**rRNA**) molecules fold into characteristic secondary structures as a consequence of intramolecular base-pairing interactions (Figure 10.20). The different species of rRNA are generally referred to according to their **sedimentation coefficients**¹, which are a rough measure of their relative size (Figure 10.21).

Ribosomes are composed of two subunits of different sizes that dissociate from each other if the Mg^{2+} concentration is below 10^{-3} M. Each subunit is a supramolecular assembly of proteins and RNA and has a total mass of 10^6 Da or more. *E. coli* ribosomal subunits have sedimentation coefficients of 30S (the small subunit) and 50S (the large subunit). Eukaryotic ribosomes are somewhat larger than prokaryotic ribosomes, consisting of 40S and 60S subunits. More than 80% of total cellular RNA is represented by the various forms of rRNA.

¹Sedimentation coefficients are a measure of the velocity with which a particle sediments in a centrifugal force field. Sedimentation coefficients are expressed in *Svedbergs* (symbolized S), named to honor The Svedberg, developer of the ultracentrifuge. One S = 10^{-13} s.

Prokaryotes:**Eukaryotes:**

Figure 10.19 Transcription and translation of mRNA molecules in prokaryotic versus eukaryotic cells.

Ribosomal RNAs characteristically contain a number of specially modified nucleotides, including **pseudouridine** residues, **ribothymidylic acid**, and methylated bases (Figure 10.22). The central role of ribosomes is protein biosynthesis: The genetic information in the nucleotide sequence of an mRNA is translated into the amino acid sequence of a polypeptide chain by ribosomes.

Transfer RNAs Carry Amino Acids to Ribosomes for Use in Protein Synthesis Transfer RNAs (**tRNAs**) serve as the carrier of amino acids for protein synthesis. tRNA molecules also fold into a characteristic secondary structure (Figure 10.23). tRNAs are small RNA molecules containing 73 to 94 residues, a substantial number of which are methylated or otherwise unusually modified. Each of the 20 amino acids in proteins has at least one unique tRNA species dedicated to chauffeuring its delivery to ribosomes for insertion into growing polypeptide chains, and some amino acids are served by several tRNAs. In eukaryotes, there are discrete sets of tRNA molecules for each site of protein synthesis—the cytoplasm, the mitochondrion, and in plant cells, the chloroplast. All tRNA molecules possess a 3'-terminal nucleotide sequence that reads **-CCA**, and the amino acid is carried to the ribosome attached as an acyl ester to the free 3'-OH

Figure 10.20 Ribosomal RNA has a complex secondary structure due to many intrastrand hydrogen bonds. The gray line in this figure traces a polynucleotide chain consisting of more than 1000 nucleotides. Aligned regions represent H-bonded complementary base sequences.

Figure 10.21 The organization and composition of prokaryotic and eukaryotic ribosomes.

Figure 10.22 Unusual bases in RNA.

Figure 10.23 Transfer RNA has a complex secondary structure due to many intrastrand hydrogen bonds. The black lines represent base-paired nucleotides in the sequence.

of the terminal A residue. These **aminoacyl-tRNAs** are the substrates of protein synthesis, the amino acid being transferred to the carboxyl end of a growing polypeptide. The peptide bond-forming reaction is catalyzed not by a protein but by the large (23S or 28S) rRNA within the large ribosomal subunit.

Small Nuclear RNAs Mediate the Splicing of Eukaryotic Gene Transcripts (hnRNA) into mRNA Small nuclear RNAs, or snRNAs, are a class of RNA molecules found in eukaryotic cells, principally in the nucleus. They contain from 100 to about 200 nucleotides, some of which, like tRNA and rRNA, are methylated or otherwise modified. No snRNA exists as naked RNA. Instead, snRNA is found in stable complexes with specific proteins forming **small nuclear ribonucleoprotein particles**, or **snRNPs**, which are about 10S in size. Their occurrence in eukaryotes, their location in the nucleus, and their relative abundance (1% to 10% of the number of ribosomes)

are significant clues to their biological purpose: snRNPs are important in the processing of eukaryotic gene transcripts (hnRNA) into mature messenger RNA for export from the nucleus to the cytoplasm (Figure 10.19).

A Variety of RNAs Serve Regulatory Roles The twenty-first century has witnessed a significant revision of the dogma of molecular biology as summarized by DNA→RNA→protein, which confined RNA to information transfer (mRNA), processing (snRNPs), and protein synthesis (rRNA and tRNA). This revision has been driven by discoveries showing that RNA molecules act in a multitude of ways to regulate biological processes as diverse as gene expression, chromatin organization, and programmed cell death. The next two sections summarize these newfound roles for RNA and the classes of RNA molecules that carry them out.

Small RNAs Serve a Number of Roles, Including Gene Silencing A class of RNA molecules even smaller than tRNAs is the **small RNAs**, so-called because they are only 21 to 28 nucleotides long. Some refer to this class as the **noncoding RNAs** (or **ncRNAs**). Others refer to small RNAs as **regulatory RNAs**, because virtually every step along the pathway of gene expression can be regulated by one or another small RNA. Small RNAs are involved in a number of novel biological functions. These small RNAs can target DNA or RNA through complementary base pairing. Base pairing of the small RNA with particular nucleotide sequences in the target is called *direct readout*.

Small RNAs are classified into a number of subclasses on the basis of their function. **RNA interference (RNAi)** is mediated by one subclass, the **small interfering RNAs (siRNAs)**. siRNAs disrupt gene expression by blocking specific protein production, even though the mRNA encoding the protein has been synthesized. The 21- to 23-nucleotide-long siRNAs act by base pairing with complementary sequences within a particular mRNA to form regions of double-stranded RNA (dsRNA). These dsRNA regions are then specifically degraded, eliminating the mRNA from the cell. Thus, RNAi is a mechanism to silence the expression of specific genes, even after they have been transcribed, a phenomenon referred to as **gene silencing**. RNAi is also implicated in modifying the structure of chromatin and causing large-scale influences in gene expression.

Another subclass, the **micro RNAs (miRNAs)** control developmental timing by base pairing with and preventing the translation of certain mRNAs, thus blocking the synthesis of specific proteins. Thus, miRNAs also act in gene silencing. However, unlike siRNAs, miRNAs (22 nucleotides long) do not cause mRNA degradation. Hundreds of different miRNAs have been described from human cells and have been shown to target most human mRNAs. As such, miRNAs are believed to influence essentially all aspects of human development and human disease.

A third subclass is the **small nucleolar RNAs (snoRNAs)**. snoRNAs (60 to 300 nucleotides long) are catalysts that, in conjunction with specific snoRNA-binding proteins, accomplish some of the chemical modifications found in tRNA, rRNA, and even DNA (see Figure 10.22, for example). **Small RNAs** in bacteria (known by the acronym **sRNAs**) play an important role altering gene expression in response to stressful environmental situations.

Long Noncoding RNAs Are Another Class of Regulatory RNAs **Long noncoding RNAs**, or **lincRNAs**, are RNA transcripts longer than 200 nucleotides. They are transcribed from DNA regions lying between genes and thus are sometimes referred to as long intergenic noncoding RNAs or long intervening noncoding RNAs. Those lincRNAs that remain in the nucleus play roles in the regulation of chromatin structure and gene repression in the nucleus. On the other hand, despite being classified as noncoding, lincRNAs that gain access to the cytoplasm may be translated into micropeptides (40 or so amino acid residues), with diverse functions. Another class of long noncoding RNAs, the **lncRNAs**, bind proteins or nucleic acids in a sequence-specific manner and are implicated in several chronic diseases.

A Deeper Look

The RNA World and Early Evolution

Proteins are encoded by nucleotide sequences in DNA. DNA replication depends on the activity of protein enzymes. These two statements form a chicken and egg paradox: Which came first in evolution—DNA or protein? Neither, it seems. The 1989 Nobel Prize in Chemistry was awarded to Thomas Cech and Sidney Altman for their discovery that RNA molecules are not only informational, but also may be catalytic. Three basic assumptions about the prebiotic RNA world are (1) RNA replication maintained information-carrying RNAs, (2) Watson–Crick base pairing was essential to RNA replication, and (3) genetically encoded proteins were unavailable as catalysts. The challenge shifts to explaining the origin of nucleotides and their polymerization to form RNA.

Adenine exists in outer space and is found in comets and meteorites. A likely source is conversion of aminoimidazolecarbonitrile to adenine. (Aminoimidazolecarbonitrile is a tetramer of HCN; adenine is a pentamer.)

Structures of aminoimidazolecarbonitrile and adenine. Adapted from Glaser, R., et al., 2007. Adenine synthesis in interstellar space: Mechanisms of prebiotic pyrimidine-ring formation of monocyclic HCN-pentamers. *Astrobiology* 7:455–470.

Glycolaldehyde can combine with other simple compounds to form ribose (and glucose). Glycolaldehyde has been detected in a gas cloud at the center of the Milky Way, our galaxy. (Acetic acid and methyl formate have the same eight atoms as glycolaldehyde; these two useful precursor molecules have also been detected in intergalactic clouds.) Inorganic phosphate, the remaining ingredient

in nucleotides, is a common component in naturally occurring aqueous solutions. Its negative charge allows it to interact readily with positively charged mineral surfaces, upon which the first nucleotides may have spontaneously assembled. Cyclic nucleotides such as cAMP (3', 5'-cyclic AMP) and cGMP (3', 5'-cyclic GMP) are formed spontaneously and accumulate under mild conditions in the presence of formamide. Recent studies show that the chemical formation of short RNA polynucleotides from such cyclic nucleotides is thermodynamically favorable in the absence of enzymes. These tantalizing facts are bright spots along the dim thread that connects us to our distant past. The RNA world is an attractive hypothesis.

10.5c The Chemical Differences between DNA and RNA Have Biological Significance

Two fundamental chemical differences distinguish DNA from RNA:

1. DNA contains 2-deoxyribose instead of ribose.
2. DNA contains thymine instead of uracil.

What are the consequences of these differences, and do they hold any significance in common? An argument can be made that, because of these differences, DNA is chemically more stable than RNA. The greater stability of DNA over RNA is consistent with the respective roles these macromolecules have assumed in heredity and information transfer.

Consider first why DNA contains thymine instead of uracil. The key observation is that *cytosine deaminates to form uracil* at a finite rate in vivo (Figure 10.24). Because C in one DNA strand pairs with G in the other strand, whereas U would pair with A, conversion of a C to a U could potentially result in a heritable change of a C:G pair to a U:A pair. Such a change in nucleotide sequence would constitute a *mutation* in the DNA. To prevent this C deamination from leading to permanent changes in nucleotide sequence, a cellular repair mechanism proofreads DNA, and when a U

Figure 10.24 The deamination of cytosine forms uracil.

arising from C deamination is encountered, it is treated as inappropriate and is replaced by a C. If DNA normally contained U rather than T, this repair system could not readily distinguish U formed by C deamination from U correctly paired with A. However, the U in DNA is 5-methyl-U or, as it is conventionally known, thymine (Figure 10.25). That is, the 5-methyl group on T labels it as if to say “this U belongs; do not replace it.”

The other chemical difference between RNA and DNA is that the ribose 2'-OH group on each nucleotide in RNA is absent in DNA. Consequently, the ubiquitous 3'-O of polynucleotide backbones lacks a hydroxyl neighbor in DNA. This difference leads to a greater resistance of DNA to alkaline hydrolysis, examined in detail in the following section. To view it another way, RNA is less stable than DNA because its 2'-OH group makes the 3'-phosphodiester bond susceptible to nucleophilic cleavage (Figure 10.26). For just this reason, it is selectively advantageous for the heritable form of genetic information to be DNA rather than RNA.

Figure 10.25 The 5-methyl group, highlighted in blue, on thymine labels it as a special kind of uracil.

10.6 | Are Nucleic Acids Susceptible to Hydrolysis?

Most reactions of nucleic acid hydrolysis break phosphodiester bonds in the polynucleotide backbone even though such bonds are among the most stable chemical bonds found in biological molecules. In the laboratory, hydrolysis of polynucleotides is used to generate smaller fragments that are easier to manipulate and study.

10.6a RNA Is Susceptible to Hydrolysis by Base, but DNA Is Not

RNA is relatively resistant to the effects of dilute acid, but gentle treatment of DNA with 1 *mM* HCl leads to hydrolysis of purine glycosidic bonds and the loss of purine bases from the DNA. The glycosidic bonds between pyrimidine bases and 2'-deoxyribose are not affected, and in this case, the polynucleotide's sugar-phosphate backbone remains intact. The purine-free polynucleotide product is called **apurinic acid**.

DNA is not susceptible to alkaline hydrolysis. On the other hand, RNA is alkali labile and is readily hydrolyzed by hydroxide ions (Figure 10.26). DNA has no 2'-OH; therefore, DNA is alkali stable.

10.6b The Enzymes That Hydrolyze Nucleic Acids Are Phosphodiesterases

Enzymes that hydrolyze nucleic acids are called **nucleases**. Virtually all cells contain various nucleases that serve important housekeeping roles in the normal course of nucleic acid metabolism. Organs that provide digestive fluids, such as the pancreas, are rich in nucleases and secrete substantial amounts to hydrolyze ingested nucleic acids. Fungi and snake venom are often good sources of nucleases. As a class, nucleases are **phosphodiesterases** because they catalyze the cleavage of phosphodiester bonds by H₂O. Because each internal phosphate in a polynucleotide backbone is involved in two phosphoester linkages, cleavage can potentially occur on either side of the phosphorus (Figure 10.27). Convention labels the 3'-side as *a* and the 5'-side as *b*. Enzymes or reactions that hydrolyze nucleic acids are characterized as acting at either *a* or *b*. A second convention denotes whether the nucleic acid chain was cleaved at some internal location, *endo*, or whether a terminal nucleotide residue was hydrolytically removed, *exo*. Note that *exo a* cleavage occurs at the 3'-end of the polymer, whereas *exo b* cleavage involves attack at the 5'-terminus (Figure 10.27).

10.6c Nucleases Differ in Their Specificity for Different Forms of Nucleic Acid

Nucleases play an indispensable role in the cellular breakdown of nucleic acids and salvage of their constituent parts. Nucleases also participate in many other cellular functions, including (1) aspects of DNA metabolism, such as replication and repair;

Complete hydrolysis of RNA by alkali yields a random mixture of 2'-NMPs and 3'-NMPs.

Figure 10.26 Alkaline hydrolysis of RNA. The defining 2'-OH of RNA is highlighted in yellow. The vertical lines represent ribose; the diagonals the phosphodiester linkages joining successive nucleotides. Nucleophilic attack by OH^- on the P atom leads to 5'-phosphoester cleavage and random hydrolysis of the cyclic 2',3'-phosphodiester intermediate to give a mixture of 2'- and 3'-nucleoside monophosphate products.

Figure 10.27 Cleavage in polynucleotide chains. (a) Diagram showing the definition of the *a* and *b* sides of the phosphodiester bridge. (b) Cleavage on the *a* side leaves the phosphate attached to the 5'-position of the adjacent nucleotide, while (c) *b*-side hydrolysis yields 3'-phosphate products.

(2) aspects of RNA metabolism, such as splicing the primary gene transcript, processing of mRNA, and RNAi; (3) rearrangements of genetic material, such as recombination and transposition; (4) host defense mechanisms against foreign nucleic acid molecules; and (5) the immune response, through assembly of immunoglobulin genes. Some nucleases are not proteins but instead are catalytic RNA molecules.

Like most enzymes, nucleases exhibit selectivity or *specificity* for the nature of the substance on which they act. That is, some nucleases act only on DNA (**DNases**), whereas others are specific for RNA (the **RNases**). Still others are nonspecific and are referred to simply as nucleases. Nucleases may also show specificity for only single-stranded nucleic acids or may act only on double helices. Some display a decided preference for acting only at certain bases in a polynucleotide, or as we shall see for *restriction endonucleases*, act only at a particular nucleotide sequence four to eight nucleotides (or more) in length. To the molecular biologist, nucleases are the surgical tools for the dissection and manipulation of nucleic acids in the laboratory.

10.6d Restriction Enzymes Are Nucleases That Cleave Double-Stranded DNA Molecules

Restriction endonucleases are enzymes, isolated chiefly from bacteria, that have the ability to cleave double-stranded DNA. The term *restriction* comes from the capacity of prokaryotes to defend against or restrict the possibility of takeover by foreign DNA that might gain entry into their cells. Prokaryotes degrade foreign DNA by using their unique restriction enzymes to chop it into relatively large but noninfective fragments. Restriction enzymes are classified into three types: I, II, or III. Types I and III require ATP to hydrolyze DNA and can also catalyze the chemical modification of DNA through the addition of methyl groups to specific bases. Type I restriction endonucleases cleave DNA randomly, whereas type III recognize specific nucleotide sequences within dsDNA and cut the DNA at or near these sites.

10.6e Type II Restriction Endonucleases Are Useful for Manipulating DNA in the Lab

Type II restriction enzymes have received widespread application in the cloning and sequencing of DNA molecules. Their hydrolytic activity is not ATP dependent, and they do not modify DNA by methylation or other means. Most important, they cut

DNA within or near particular nucleotide sequences that they specifically recognize. These recognition sequences are typically four or six nucleotides in length and have a twofold axis of symmetry. For example, *E. coli* has a restriction enzyme, *EcoRI*, that recognizes the hexanucleotide sequence GAATTC:

Note the twofold symmetry: The sequence read 5'→3' is the same in both strands.

When *EcoRI* encounters this sequence in dsDNA, it causes a staggered, double-stranded break by hydrolyzing each chain between the G and A residues:

Staggered cleavage results in fragments with protruding single-stranded 5'-ends:

Because the protruding termini of *Eco*RI fragments have complementary base sequences, they can form base pairs with one another.

Therefore, DNA restriction fragments having such sticky ends can be joined together to create new combinations of DNA sequence. If fragments derived from DNA molecules of different origins are combined, novel recombinant forms of DNA are created.

EcoRI leaves staggered 5'-termini. Other restriction enzymes, such as *PstI*, which recognizes the sequence 5'-CTGCAG-3' and cleaves between A and G, produce cohesive staggered 3'-ends. Still others, such as *BalI*, act at the center of the twofold symmetry axis of their recognition site and generate blunt ends that are noncohesive. *BalI* recognizes 5'-TGGCCA-3' and cuts between G and C.

Table 10.2 lists some of the commonly used restriction endonucleases and their recognition sites. Different restriction enzymes sometimes recognize and cleave within identical target sequences. Such enzymes are called **isoschizomers**, meaning that they cut at the same site; for example, *Mbo*I and *Sau*3A are isoschizomers.

Restriction Fragment Size Assuming random distribution and equimolar proportions for the four nucleotides in DNA, a particular tetranucleotide sequence should occur every 4⁴ nucleotides, or every 256 bases. Therefore, the fragments generated by a restriction enzyme that acts at a four-nucleotide sequence should average about 250 bp in length. Six-cutters, enzymes such as *EcoRI* or *BamHI*, will find their unique hexanucleotide sequences, on average, once in every 4096 (4⁶) bp of length. Because the genetic code is a triplet code with three successive bases in a DNA strand specifying one amino acid in a polypeptide sequence, and because polypeptides typically contain at most 1000 amino acid residues, the fragments generated by six-cutters are approximately the size of prokaryotic genes. This property makes these enzymes useful in the construction and cloning of genetically useful recombinant DNA molecules. For the isolation of even larger nucleotide sequences, such as those of genes

Table 10.2 Some Common Restriction Endonucleases and Their Restriction Sites

Over 3000 restriction enzymes have been characterized. They are named by italicized three-letter codes; the first is a capital letter denoting the genus of the organism of origin, and the next two letters are an abbreviation of the particular species. Because prokaryotes often contain more than one restriction enzyme, the various representatives are assigned letter and number codes as they are identified. Thus, *EcoRI* is the initial restriction endonuclease isolated from *Escherichia coli*, strain R. With one exception (*NciI*), all known type II restriction endonucleases generate fragments with 5'-PO₄ and 3'-OH ends.

Enzyme	Common Isoschizomers	Recognition Sequence	Compatible Cohesive Ends
<i>AluI</i>		AG↓CT	Blunt

encoding large polypeptides (or those of eukaryotic genes that are disrupted by large introns), partial or limited digestion of DNA by restriction enzymes can be employed. However, restriction endonucleases that cut only at specific nucleotide sequences 8 or even 13 nucleotides in length are also available, such as *NotI* and *SfiI*.

10.6f Restriction Endonucleases Can Be Used to Map the Structure of a DNA Fragment

The application of these sequence-specific nucleases to problems in molecular biology is considered in detail in Chapter 12, but one prominent application is described here. Because restriction endonucleases cut dsDNA at unique sites to generate large fragments, they provide a means for mapping DNA molecules that are many kilobase pairs in length. Restriction digestion of a DNA molecule is in many ways analogous to proteolytic digestion of a protein by an enzyme such as trypsin: The restriction endonuclease acts only at its specific sites so that a discrete set of nucleic acid fragments is generated. This action is analogous to trypsin cleavage only at Arg and Lys residues to yield a particular set of tryptic peptides from a given protein. The restriction fragments represent a unique collection of different-sized

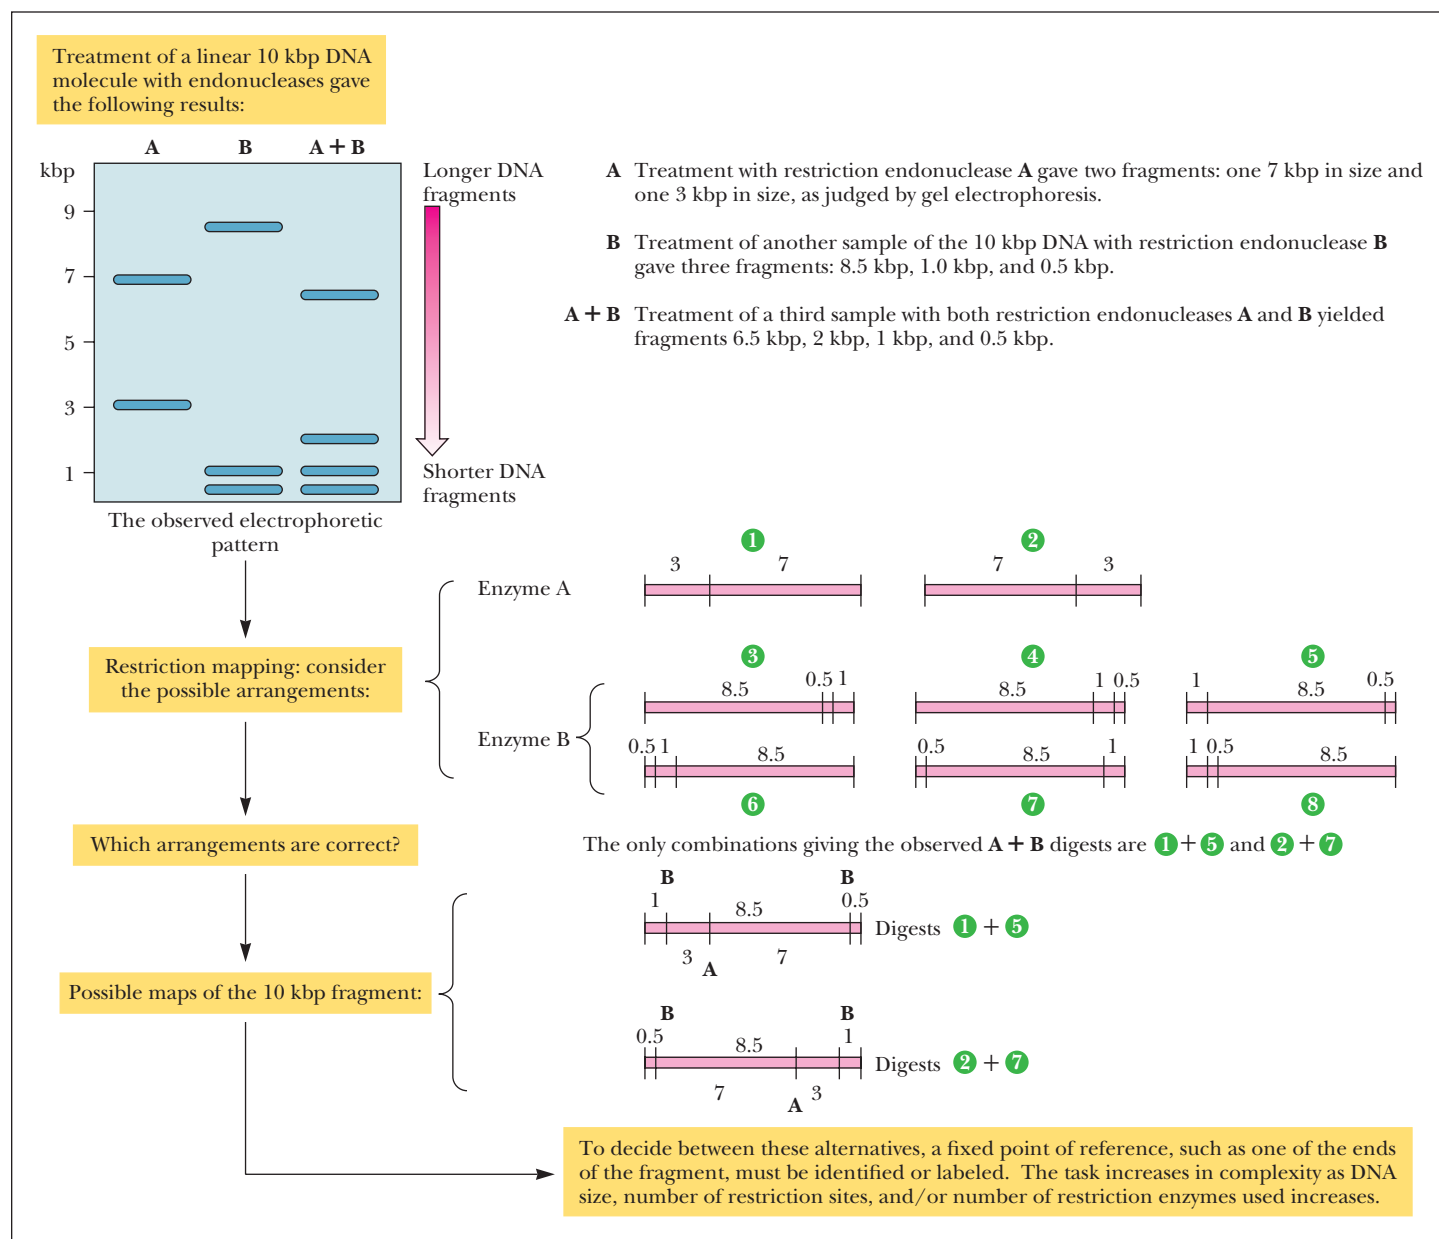

Figure 10.28 Restriction mapping of a DNA molecule as determined by an analysis of the electrophoretic pattern obtained for different restriction endonuclease digests. (Keep in mind that a dsDNA molecule has a unique nucleotide sequence and therefore a definite polarity; thus, fragments from one end are distinctly different from fragments derived from the other end.)

DNA pieces. Fortunately, this complex mixture can be resolved by *electrophoresis* (see the Chapter 5 A Deeper Look box “Techniques Used in Protein Purification”). Electrophoresis of DNA molecules on gels of restricted pore size (as formed in agarose or polyacrylamide media) separates them according to size, the largest being slowed in their migration through the gel pores, whereas the smallest move relatively unhindered. Figure 10.28 shows a hypothetical electrophoretogram obtained for a DNA molecule treated with two different restriction nucleases, alone and in combination. Just as cleavage of a protein with different proteases to generate overlapping fragments allows an ordering of the peptides, restriction fragments can be ordered or mapped according to their sizes, as deduced from the patterns depicted in Figure 10.28.

Foundational Biochemistry Things You Should Know after Reading Chapter 10.

- Nucleotides are composed of either a pyrimidine or a purine base, a ribose, and phosphate.
- Nucleotides participate in virtually all aspects of metabolism.
- Nucleic acids are polynucleotides.
- The two kinds of nucleic acid are DNA and RNA.
- DNA is the repository of genetic information in cells.
- RNA is involved in the expression of genetic information through the processes of transcription and translation.
- Pyrimidines and purines are heterocyclic aromatic substances containing two (pyrimidines) or four (purines) nitrogen atoms in their ring structures.
- The three principal pyrimidines are cytosine, uracil, and thymine.
- The two principal purines are adenine and guanine.
- Purines and pyrimidines undergo keto–enol tautomeric shifts.
- The particular keto or enol form of a nitrogenous base affects its H-bonding possibilities.
- The aromaticity of pyrimidines and purines endows them with UV absorbance properties.
- Nucleosides are formed when ribose (or deoxyribose) is attached to a nitrogenous base via a β -N-glycosidic bond.
- Nucleotides are formed when phosphoric acid is esterified to an —OH group of the ribose of a nucleoside.
- Cyclic nucleotides result when the phosphate group forms ester linkages with two ribose —OH groups.
- Nucleoside diphosphates (NDPs) and nucleoside triphosphates (NTPs) are nucleotides with two or three phosphoryl groups.
- NDPs and NTPs are polyprotic acids.
- NTPs are the carriers of chemical energy.
- Nucleic acids are polymers of nucleotides linked 3' to 5' by phosphodiester bridges to form a sugar–phosphate backbone from which the bases project.
- The sequence of bases along the sugar–phosphate backbone is the defining characteristic of a nucleic acid.
- DNA is found in chromosomes as the genetic material.
- RNA has as its central role the transfer of information from DNA to protein.
- The fundamental structure of DNA is a double helix that is maintained by base pairing between a purine base in one strand and a pyrimidine base in the other.
- The canonical base pairs are A:T and G:C.
- The information of DNA is encoded in digital form.
- Messenger RNA (mRNA) carries the sequence information for synthesis of a protein.
- Ribosomal RNA (rRNA) provides both the structural framework and the protein-synthesizing function of ribosomes.
- Transfer RNAs (tRNAs) deliver amino acids in the form of aminoacyl-tRNAs for use in protein synthesis.
- Small nuclear ribonucleoproteins (snRNPs) mediate the splicing of eukaryotic gene transcripts to form mature mRNAs.
- Small RNAs and long noncoding RNAs serve a variety of regulatory roles in cells.
- The chemical differences between DNA and RNA—thymine vs. uracil, presence or absence of 2'-OH group—have important biological consequences.
- DNA is acid labile; RNA is not.
- RNA is susceptible to hydrolysis by base because of its 2'-OH group; DNA lacks this —OH and is not susceptible to alkaline hydrolysis.
- Enzymes that hydrolyze the phosphoester bonds of nucleic acids are called nucleases.
- Nucleases differ in their specificity for the different forms of nucleic acid, such as DNA versus RNA or single stranded versus double stranded.
- Type II restriction endonucleases are nucleases that cleave double-stranded DNA at specific base sequences. These enzymes are useful for in vitro manipulation of DNA molecules.
- Restriction endonucleases can be used to map the structure of DNA molecules.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- 1. The Structure and Ionization Properties of Nucleotides** Draw the principal ionic species of 5'-GMP occurring at pH 2.
- 2. Oligonucleotide Structure** Draw the chemical structure of pACG.
- 3. Chemistry of Nucleosides** For each part below, select the term that applies when describing the chemistry of nucleosides:
 - a. pentose, hexose, or heptose
 - b. D or L
 - c. ketose or aldose
 - d. α or β
 - e. pyranose or furanose
- 4. Tautomerism** Draw all the tautomeric forms of uric acid (see Figure 10.5).
- 5. Chargaff's Rules for the Base Composition of DNA** Chargaff's results (Table 10.1) yielded a molar ratio of 1.56 for A to G in human DNA, 1.75 for T to C, 1.00 for A to T, and 1.00 for G to C. Given these values, what are the approximate mole fractions of A, C, G, and T in human DNA?
- 6. Abundance of the Different Bases in the Human Genome** Results on the human genome published in *Science* (*Science* **291**:1304–1350 [2001]) indicate that the haploid human genome consists of 2.91 gigabase pairs (2.91×10^9 base pairs) and that 27% of the bases in human DNA are A. Calculate the number of A, T, G, and C residues in a typical human cell.
- 7. The Base Sequence in the Two Polynucleotide Chains of a DNA Double Helix Is Complementary** Adhering to the convention of writing nucleotide sequences in the 5'→3' direction, what is the nucleotide sequence of the DNA strand that is complementary to d-ATCGCAACTGTCCTA?

8. **Structure of Nucleic Acids** A student put together a structure of a short fragment of DNA. Identify the serious mistake that the student made in this structure.

9. **The Relationship between the Nucleotide Sequence of an mRNA and the DNA Strand from Which It Is Transcribed** Messenger RNAs are synthesized by RNA polymerases that read along a DNA template strand in the 3'→5' direction, polymerizing ribonucleotides in the 5'→3' direction (see Figure 10.19). Give the nucleotide sequence (5'→3') of the DNA template strand from which the following mRNA segment was transcribed: 5'-UAGUGACAGUUGCGAU-3'.
10. **An Antisense RNA Is an RNA That Base-Pairs with an mRNA and Prevents Its Translation** One strategy to thwart the deleterious effects of genes activated in disease states (such as cancer) is to generate antisense RNAs in affected cells. Suppose the transcription of a cancer-activated gene yielded an mRNA whose sequence included the segment 5'-UACGGUCUAAGCTGA. Which of the following is the correct nucleotide sequence (5'→3') for the template strand in a DNA duplex that would code for an antisense RNA? (Hint: Recall that the DNA strand that is not copied by RNA polymerase during transcription has a nucleotide sequence identical to that of the RNA being synthesized [except T residues are found in the DNA strand at sites where U residues occur in the RNA]).
- 5'-ATGCCAGATTCGACT
 - 5'-TACGGTCTAAGCTGA
 - 5'-TAGCGGTCTAAGCTGA
 - 5'-TCAGCTTAGACCGCTA
11. **Restriction Endonuclease Mapping of a DNA Fragment** A 10 kbp DNA fragment digested with the restriction endonuclease *EcoRI* yielded fragments 4 kbp and 6 kbp in size. When digested with *BamHI*, fragments 1, 3.5, and 5.5 kbp were generated. Concomitant digestion with both *EcoRI* and *BamHI* yielded fragments 0.5, 1, 3, and 5.5 kbp in size. Give a possible restriction map for the original fragment.
12. **Design of DNA Sequences with Overlapping Restriction Endonuclease Sites** Based on the information in Table 10.2, describe two different 20 base-pair nucleotide sequences that have restriction sites for *BamHI*, *PstI*, *SalI*, and *SmaI*. Give the sequences of the *SmaI* cleavage products of each.
13. **Calculate the Free Energy Change for Synthesis of a Polynucleotide** (Integrates with Chapter 3.) The synthesis of RNA can be summarized by the reaction:

What is the $\Delta G^{\circ}_{\text{overall}}$ for synthesis of an RNA molecule 100 nucleotides in length, assuming that the ΔG° for transfer of an NMP from an NTP to the 3'-O of polynucleotide chain is the same as the ΔG° for transfer of an NMP from an NTP to H_2O ? (Use data given in Table 3.1.)

14. **Protein-DNA Interactions** Gene expression is controlled through the interaction of proteins with specific nucleotide sequences in double-stranded DNA.
- List the kinds of noncovalent interactions that might take place between a protein and DNA.
 - How do you suppose a particular protein might specifically interact with a particular nucleotide sequence in DNA? That is, how might proteins recognize specific base sequences within the double helix?
15. **The Properties Restriction Endonucleases Must Have** Restriction endonucleases also recognize specific base sequences and then act to cleave the double-stranded DNA at a defined site. Speculate on the mechanisms by which this sequence recognition and cleavage reaction might occur by listing a set of requirements for the process to take place.
16. **The Properties That Carbohydrates Contribute to Nucleosides, Nucleotides, and Nucleic Acids** A carbohydrate group is an integral part of a nucleoside.
- What advantage does the carbohydrate provide?
 - Why might ribose be preferable for this backbone instead of glucose?
 - Why might 2-deoxyribose be preferable to ribose in some situations?
17. **Chemical Analysis of DNA** A DNA sample was analyzed and found to contain 0.1 pg phosphorus. What is the number of base pairs present in this DNA sample?
18. **How Does the Presence of Phosphate Affect the Properties of Nucleotides?** Phosphate groups are also integral parts of nucleotides, with the second and third phosphates of a nucleotide linked through phosphoric anhydride bonds, an important distinction in terms of the metabolic role of nucleotides.
- What property does a phosphate group have that a nucleoside lacks?
 - How are phosphoric anhydride bonds useful in metabolism?
 - How are phosphate anhydride bonds an advantage to the energetics of polynucleotide synthesis?
19. **Calculate the Frequency of Occurrence of an RNAi Target Sequence** The RNAs acting in RNAi are about 21 nucleotides long. To judge whether it is possible to uniquely target a particular gene with a RNA of this size, consider the following calculation: What is the expected frequency of occurrence of a specific 21-nucleotide sequence?
20. **Calculate the Length of a Nucleotide Sequence Whose Expected Frequency Is Once per Haploid Human Genome** The haploid human genome consists of 3×10^9 base pairs. Using the logic in problem 19, one can calculate the minimum length of a unique DNA sequence expected to occur by chance just once in the human genome. That is, what is the length of an oligonucleotide whose expected frequency of occurrence is once every 3×10^9 bp?
21. **Design a Sequencing Strategy for Nucleic Acids** Snake venom phosphodiesterase is an *a*-specific exonuclease (Figure 10.27) that acts equally well on single-stranded RNA or DNA. Design a protocol based on snake venom phosphodiesterase that would allow you to determine the base sequence of an oligonucleotide. Hint: Adapt the strategy for protein sequencing by Edman degradation, as described in Section 5.3 and Figure 4.8a.
22. **Calculate the Mass of DNA in a Human Cell** From the answer to problem 6 and the molecular weights of dAMP (331 Da), dCMP (307 Da), dGMP (347 Da), and dTMP (322 Da), calculate the mass (in daltons) of the DNA in a typical human cell.

- 23. The Bases of Nucleotides Serve as Information Symbols** The bases of nucleotides and polynucleotides are information symbols. Their central role in providing information content to DNA and RNA is clear. What advantages might bases as information symbols bring to the roles of nucleotides in metabolism?
- 24. Structural Complementarity in the DNA Double Helix** Structural complementarity is the key to molecular recognition, a lesson learned in Chapter 1. The quintessential example of structural complementarity in all of biology is the DNA double helix. What features of the DNA double helix exemplify structural complementarity?

Think-Pair-Share Question

Binary Code in dsDNA DNA molecules carry information dictating the order in which amino acids need to be linked to make a functional protein, the so-called genetic code. Comparisons between this genetic

code and computer codes are often made. However, computer codes are binary, consisting of a sequence of zeros and ones (0's and 1's), while the code in DNA, built from the four different nucleotides, is a quaternary code.

Consider the piece of dsDNA shown.

5'-TCAACTGGTACCTAATCCCGGGATCCGGTAATTCT-GAGCCCAGTAACT-3'

3'-AGTTGACCATGGATTAGGGCCCTAGGCCATTAAGACTC-GGGTCATTGA-5'

Devise a system by which it could serve as a source of binary code and write down the 0/1 sequence encoded in this dsDNA segment. Note that several solutions are possible. (Hint: remember Chargaff's observations.)

Structure of Nucleic Acids

11

The Structure of DNA: "A melody for the eye of the intellect, with not a note wasted."

Horace Freeland Judson
The Eighth Day of Creation

Reginald H. Garrett

◀ Renaissance masons created this double helix adorning the cathedral in Orvieto, Italy, some 500 years ago. In 1953, a double helix was shown to be the structure that lies at the heart of heredity.

Essential Question

The nucleotide sequence—the primary structure—of DNA not only determines its higher-order structure, but it is also the physical representation of genetic information in organisms. RNA sequences, as copies of specific DNA segments, direct both the higher-order structure and the function of RNA molecules in information transfer processes. **What are the higher-order structures of DNA and RNA, and what methodologies have allowed scientists to probe these structures and the functions that derive from them?**

Chapter 10 presented the structure and chemistry of nucleotides and how these units are joined via phosphodiester bonds to form nucleic acids, the biological polymers for information storage and transmission. In this chapter, we investigate biochemical methods that reveal the primary, secondary, and tertiary structure of nucleic acids. The primary structure—the sequential order of nucleotides in a polynucleotide chain—is the embodiment of genetic information. Then, we turn to the higher orders of structure in the nucleic acids—the secondary and tertiary levels—that describe how these structures exist in nature. Although the focus here is primarily on the structural and chemical properties of these macromolecules, it is fruitful to keep in mind the biological roles of these remarkable substances. We can anticipate that the cellular mechanisms for accessing and expressing genetic information, as well as reproducing it with high fidelity, will be illuminated by knowledge of the chemical and structural qualities of these polymers.

11.1 How Do Scientists Determine the Primary Structure of Nucleic Acids?

Determining the primary structure of nucleic acids—the nucleotide sequence—would seem to be a more formidable problem than amino acid sequencing of proteins, simply because nucleic acids contain only four unique monomeric units (A, C, G, and T),

Key Questions

- 11.1 How Do Scientists Determine the Primary Structure of Nucleic Acids?
- 11.2 What Sorts of Secondary Structures Can Double-Stranded DNA Molecules Adopt?
- 11.3 Can the Secondary Structure of DNA Be Denatured and Renatured?
- 11.4 How Does DNA Adopt Structures of Higher Complexity?
- 11.5 What Is the Structure of Eukaryotic Chromosomes?
- 11.6 How Can Nucleic Acids Be Synthesized Chemically?
- 11.7 What Are the Secondary and Tertiary Structures of RNA?

Figure 11.1 DNA replication yields two new DNA duplexes identical to the original DNA double helix.

whereas proteins have 20. With only four, there are *apparently* fewer specific sites for selective cleavage, distinctive sequences are more difficult to recognize, and the likelihood of ambiguity is greater. The much greater number of monomeric units in most polynucleotides compared with polypeptides is a further difficulty. However, two simple tools rendered the determination of nucleotide sequence in nucleic acids far easier than amino acid sequencing. One of these tools was the set of type II *restriction endonucleases* that cleave DNA at specific oligonucleotide sites, generating unique fragments of manageable size (see Chapter 10). The second was *gel electrophoresis*, a method capable of separating nucleic acid fragments that differ from one another in length by just a single nucleotide. As we shall see, the early successes based on these tools spawned more efficient and effective technologies for nucleic acid sequencing, so much so that now, such sequencing is extremely easy, and a new problem has emerged: the “big data” problem; that is how to interpret the information held within the more than 10^{13} base pairs’ worth of novel sequence data. This challenge is addressed by the new field of **bioinformatics**, the analysis of these data sets to reveal biologically relevant information.

11.1a The Nucleotide Sequence of DNA Can Be Determined from the Electrophoretic Migration of a Defined Set of Polynucleotide Fragments

The traditional protocol for nucleic acid sequencing has been the **chain termination** or **dideoxy method** of Frederick Sanger, which relies on enzymatic replication of the DNA to be sequenced. Very sensitive analytical techniques that can detect the newly synthesized DNA chains following electrophoretic separation are available, so Sanger sequencing could be carried out on as little as 1 attomole (amol, 10^{-18} mol) of DNA contained in less than $0.1 \mu\text{L}$ volume. (10^{-18} moles of DNA are roughly equivalent to 10^{-12} grams (pg) of 1-kb sized DNA molecules.) These analytical techniques typically rely on fluorescent detection of the DNA products.

11.1b Sanger’s Chain Termination or Dideoxy Method Uses DNA Replication to Generate a Defined Set of Polynucleotide Fragments

The rationale of the chain termination or dideoxy method is found in the biochemistry of DNA replication. DNA is a double helical molecule. In the course of its replication, the sequence of nucleotides in one strand is copied in a complementary fashion to form a new second strand by the enzyme **DNA polymerase**. Each original strand of the double helix serves as a **template** for the biosynthesis that yields two daughter DNA duplexes from the parental double helix (Figure 11.1). DNA polymerase will carry out this reaction *in vitro* in the presence of the four deoxynucleotide monomers and copy single-stranded DNA, provided a double-stranded region of DNA is artificially generated by adding a **primer**. This primer is an oligonucleotide capable of forming a short stretch of dsDNA by base pairing with the ssDNA (Figure 11.2). The primer must have a free 3′-OH end from which the new polynucleotide chain can grow as the first residue is added in the initial step of the polymerization process. DNA polymerases synthesize new strands by adding successive nucleotides in the 5′→3′ direction.

The DNA polymerase reaction: dNMP addition to the 3′-OH end of a DNA strand that is base-paired with a template strand

Figure 11.2 Primed synthesis of a DNA template by DNA polymerase, using the four deoxynucleoside triphosphates as the substrates.

The Chain Termination Protocol In the chain termination method of DNA sequencing, a DNA fragment of unknown sequence serves as a template in a polymerization reaction using DNA polymerase, usually a genetically engineered version that lacks all traces of exonuclease activity that might otherwise degrade the DNA. (DNA polymerases usually have an intrinsic exonuclease activity that allows proofreading and correction of the DNA strand being synthesized; see Chapter 28.) An appropriate oligonucleotide is used as a primer (this method is also known as the **primed synthesis method** for this reason). The reaction is run in the presence of all four deoxynucleoside triphosphates dATP, dGTP, dCTP, and dTTP, which are the substrates for DNA polymerase (Figure 11.3). In addition, the reaction mixture contains the four corresponding 2',3'-dideoxynucleotides (ddATP, ddGTP, ddCTP, and ddTTP); it is these dideoxynucleotides that give the method its name.

Because dideoxynucleotides lack 3'-OH groups, they cannot serve as acceptors for 5'-nucleotide addition in the polymerization reaction; thus, the chain is terminated where they become incorporated. The concentrations of the deoxynucleotides in each reaction mixture are significantly greater than the concentrations of the dideoxynucleotides, so incorporation of a dideoxynucleotide is infrequent. Therefore, premature chain termination is only a random, occasional event, and a population of new strands of varying length is synthesized. Nevertheless, termination, although random, occurs everywhere in the sequence. Thus, the population of newly synthesized DNAs forms a

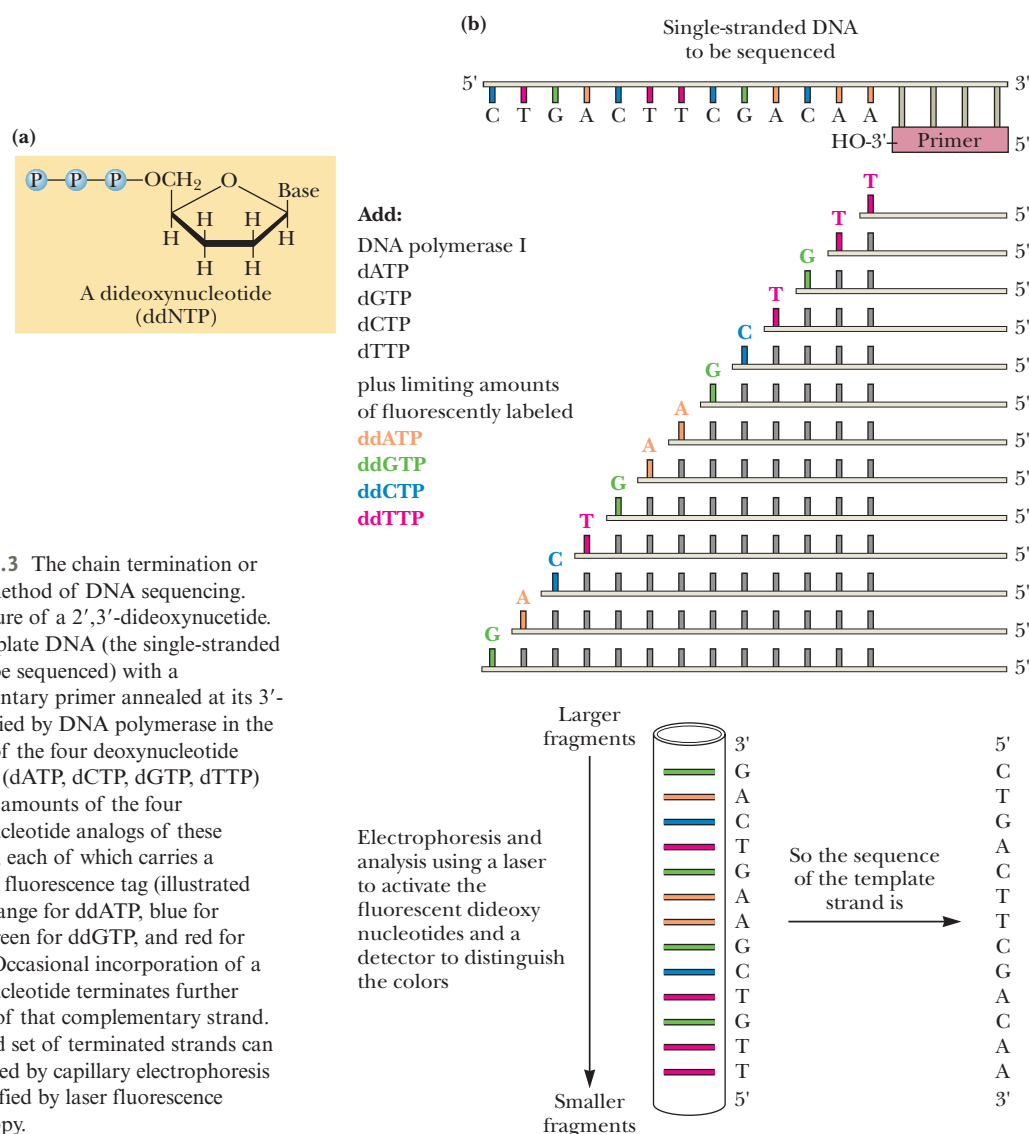

Figure 11.3 The chain termination or dideoxy method of DNA sequencing. **(a)** Structure of a 2',3'-dideoxynucleotide. **(b)** A template DNA (the single-stranded DNA to be sequenced) with a complementary primer annealed at its 3'-end is copied by DNA polymerase in the presence of the four deoxynucleoside triphosphates (dATP, dGTP, dCTP, dTTP) and small amounts of the four dideoxynucleoside triphosphates (ddATP, ddGTP, ddCTP, ddTTP), each of which carries a distinctive fluorescence tag (illustrated here as orange for ddATP, blue for ddCTP, green for ddGTP, and red for ddTTP). Occasional incorporation of a dideoxynucleotide terminates further synthesis of that complementary strand. The nested set of terminated strands can be separated by capillary electrophoresis and identified by laser fluorescence spectroscopy.

nested set of molecules that differ in length by just one nucleotide. Each newly synthesized strand has a dideoxynucleotide at its 3'-end, and each of the four dideoxynucleotides used in Sanger sequencing is distinctive because each bears a fluorescent tag of a different color. (These fluorescent tags are attached to the 5-position of pyrimidine dideoxynucleotides or the 7-position of purine dideoxynucleotides, where these tags do not impair the ability of DNA polymerase to add them to a growing polynucleotide chain.) The color of a particular fluorescence (as in orange for ddA, blue for ddC, green for ddG, and red for ddT) reveals which base was specified by the template and incorporated by DNA polymerase at that spot.

Reading Dideoxy Sequencing Gels The sequencing products are visualized by fluorescence spectroscopy following their separation according to size by capillary electrophoresis (Figure 11.3). Because the smallest fragments migrate fastest upon electrophoresis and because fragments differing by only a single nucleotide in length are readily resolved, the sequence of nucleotides in the set of newly synthesized DNA fragments is given by the order of the fluorescent colors emerging from the capillary. Thus, the gel in Figure 11.3 is read TTGTCGAAGTCAG (5'→3'). Because of the way DNA polymerase acts, this observed sequence is complementary to the corresponding unknown template sequence. Knowing this, the template sequence now can be written CTGACTTCGACAA (5'→3').

Sanger sequencing has been fully automated. Automation is achieved through the use of robotics for preparing the samples, running the DNA sequencing reactions, loading the chain-terminated DNA fragments onto capillary electrophoresis tubes, performing the electrophoresis, and imaging the results for computer analysis. These advances made it feasible to sequence the entire genomes of organisms.

Careers in Chemistry

Sabrina Farais

Sabrina Farais was born in Stockton, California to two working parents who were not afforded academic opportunities beyond the high school level. They worked hard to provide them to Sabrina and she credits her parents for her work ethic and integrity. Farais went from not knowing what a GPA was to earning her biochemistry degree from Oklahoma State University and becoming a lab director in the medical marijuana industry, working in tandem with the Oklahoma Medical Marijuana Authority (OMMA).

Currently, she tests medical cannabis products for mycotoxins, residual solvents, microbial growth and heavy metals to ensure the safety of the patients who receive them. Her research has also led to lipid-based products such as balms, lotions, and waxes. Sabrina continues her pursuit of knowledge to this day and offers this advice to students who feel that the STEM field has an exclusionary culture: “Don’t let that scare you away from your passion. Experience is strength and challenges become easier as you become stronger.”

11.1c Next-Generation Sequencing by Synthesis

The enormous significance of DNA sequence information to fundamental questions in biology, medicine, and personal health has been the driving force for the development of ever more rapid and efficient DNA sequencing technologies, the so-called next-generation (“next-gen”) or ultra-high-throughput (UHT) sequencing. None of this would have been possible without extraordinary advances in nanotechnology. Nanobiotechnology has developed materials and methods allowing manipulation and analysis of extremely small amounts of biomolecules, such as DNA. Indeed, in some instances, the ultimate goal—studies on single molecules—has been met.

Most commercially available sequencers have a common attribute: As in the Sanger or capillary electrophoresis protocols, they perform **sequencing by synthesis (SBS)**, where DNA polymerase catalyzes the synthesis of a complementary strand. The

next-gen sequencers have the advantage in that they can directly detect the addition of each base and record that information in digital form for computer analysis. The digital record also contains information that enables quantification of the amount of each DNA molecule within the library. Hundreds of thousands to hundreds of millions of sequencing reactions can be run at the same time on these instruments, yielding thousands of gigabases ($>10^{12}$ bases) of sequence information per run. This ability is referred to as **massively parallel sequencing**. Unlike capillary sequencers, which can read about 600 bases per DNA template, these next-gen sequencers have shorter read lengths, on the order of 150 to 250 bases per template. Their capacity for massively parallel sequencing means that read length is not a limitation because so many different overlapping DNA strands are sequenced at once. As in amino acid sequencing, the complete sequence of a DNA molecule is reconstructed by comparing the sequences of overlapping fragments.

The massively parallel DNA sequencing platforms developed by Illumina, Inc., rely on sequencing by synthesis. The Illumina protocol uses fluorescent-tagged deoxynucleotide substrates whose 3'OH terminus is blocked by an easily removed chemical group (Figure 11.4a). By using such reversible terminator substrates, this process allows only one base to be added at a time to a growing chain. Once the DNA polymerase selects the appropriate dNTP through base pairing with the template, it is added to the growing chain. Whether an A, C, G, or T was added is revealed upon laser excitation of the fluorescent tag it carries (Figure 11.4b). The fluorescent flash is recorded by a digital camera, and the information is sent to a computer. Then, both the 3'-blocking group and the bulky fluorescent tag are chemically removed, exposing a free 3'-O to the DNA polymerase, which can now select and add the next appropriate dNTP in line.

In Illumina SBS sequencing, the DNA of interest is first broken into manageable 200 to 600 bp fragments. Individual fragments are processed to generate hundreds of millions of identical single-stranded DNA templates (called “clusters”). Individual DNA molecules within the cluster are immobilized by base pairing with primers attached to the surface of a glass sheet. The sequencing process begins when reagents for sequencing by synthesis are flowed across the sheet. In the reaction cycle, a nucleotide substrate (A, C, G, or T) will be added to a growing primer, as chosen by base pairing with the template. Let's suppose the first unpaired base in the primer-immobilized template is G. The DNA polymerase will select the dCTP representative among the cleavable 3'-O-blocked-dNTP reversible terminator substrate choices and extend the chain. The fluorescence of the specific dCTP tag reports its presence at this position, and this information is digitally recorded. In the next step, both the 3'-O-blocking group and the fluorescent tag are removed. The 3'-O-terminal C on the growing “sequence by synthesis” strand now has a free 3'-OH group that can accept the next incoming nucleotide, as determined by base pairing with the template at the next base in line. The process continues in this manner until completed. Since each cycle provides a unique fluorescent signal identifying the base just incorporated (and thus, the template base that was available to the DNA polymerase), information on the template sequence is accumulated. Illumina sequencing is currently the most widely used sequencing protocol. The latest Illumina sequencing instruments take less than two days and produce in excess of 3000 Gb of sequence data per run.

11.1d High-Throughput DNA Sequencing Based on Proton Detection

As shown in Figure 11.2, the DNA polymerase reaction produces pyrophosphate and an H^+ with each dNTP addition to the growing polynucleotide strand (see Box, Figure 11.2 for the DNA polymerase reaction). Detection of this proton release is the basis for a sequencing by synthesis strategy developed by Ion Torrent. Semiconductor chips (such as those used in the electronics industry) are the platform for this technology. These chips consist of an array of microwells, placed over dedicated ion sensors. Primed DNA strands to be sequenced are captured in individual microwells. Since each microwell contains a unique population of identical DNA strands, many different sequences can be determined in parallel on the same chip. Next, either dATP,

(a) 3'-O- blocked reversible terminator

(b)

Figure 11.4 The Illumina SBS sequencing protocol. (a) Generic structure of the fluorescent dye-tagged, 3'-O-blocked reversible deoxynucleotide substrates used in Illumina sequencing protocols. (Adapted from Figure 1 in Chen, F., Dong, M., Ge, M., Zhu, L., et al., 2013. The history and advances of reversible terminators used in new generations of sequencing technology. *Genomics, Proteomics, and Bioinformatics* 11:34–40). (b) The Illumina SBS sequencing cycle. Primer extension through DNA polymerase selection of a deoxynucleotide substrate through base pairing with the template strand adds the appropriate 3'-O-blocked fluorescence-tagged deoxynucleotide. The deoxynucleotide added is identified by its unique fluorescence emission following laser excitation (Step 2, “read color”), followed by cleavage and removal of the fluorescence tag and the 3'-O-blocking group (Step 3, remove color and 3'-blocking group”). Wash and repeat. (Adapted from Figure 3 in Chen, F., Dong, M., Ge, M., Zhu, L., et al., 2013. The history and advances of reversible terminators used in new generations of sequencing technology. *Genomics, Proteomics, and Bioinformatics* 11:34–40).

dCTP, dGTP, or dTTP is introduced into the microwells in the presence of DNA polymerase. If the introduced dNTP is complementary to the unpaired base on the primed DNA strand being sequenced, DNA polymerase incorporates it, and an H^+ is released, which causes a pH change. This pH change is detected by the semiconductor ion sensor, which converts this chemical information into a digital signal in the form of a voltage change. As dNTPs are flowed one after the other through the microwells, voltage changes are recorded in the various microwells each time DNA polymerase adds a nucleotide to the growing chain. The record of voltage changes within each microwell reveals the sequence of the DNA strand in that well. The advantages of this methodology are rapid sequencing at a lower cost.

11.1e Single-Molecule Real-Time Sequencing

A disadvantage of Illumina and Ion Torrent sequencing systems is the short-read length they generate—on the order of only 150 to 200 nucleotides per DNA template. This disadvantage can usually be offset by running large numbers of sequence experiments concurrently with overlapping DNA sets. However, eukaryotic genomes contain large regions of repetitive DNA where the same sequence units are repeated over and over again. Indeed, 30% of the human genomes consists of thousands of copies of such tandemly repeated sequences, some about 300 bp, others, thousands of bp in length. It is very difficult to pinpoint the beginning and ends of tandemly repeated sequences using short-read sequencing technologies.

Single-molecule real-time (SMRT) sequencing, developed by Pacific BioSciences (PacBio), offers an alternative approach to overcome many of these limitations. SMRT sequencing yields read lengths that exceed 10 kbp on average (Figure 11.5). It is real-time sequencing because it doesn't require a pause between read steps. SMRT sequencing can resolve the precise location and sequence of long repetitive regions, a real advantage in genome analysis.

Figure 11.5 Single-molecule real-time (SMRT) sequencing. **(a)** Hairpin loops (green) of DNA are ligated to the double-stranded DNA (yellow/blue) to be sequenced. Note the distinct single-stranded regions and the double-stranded 'primer' region (orange) of the left-hand loop. A sample of this DNA construct, called an SMRTbell, is loaded into a chip called the SMRT cell. A single DNA polymerase molecule (gray) binds to the primer end in the DNA loop. Each SMRT cell has from 35,000 to 75,000 wells, each of which contains a different DNA SMRTbell sample with its single DNA polymerase. The four deoxynucleotide substrates consist of the usual dNTP structure, each with a distinctive fluorophore triphosphate fluorescent tag attached to the terminal phosphate group of the dNTP. The four different phosphorfluorophore-dNTP substrates are flooded into the wells containing the various SMRTbell samples. The appropriate deoxynucleotide substrate, as determined by base-pairing with the SMRT template, is captured by the DNA polymerase and can be identified by its characteristic light pulse upon laser excitation. DNA polymerase action adds this chosen substrate as a 3'-O terminal-dNMP, releasing the phosphorfluorophore tag, which is washed away. The sequence of the DNA sample is determined by recording the distinctive light pulses over time, as the DNA polymerase moves along its template, selecting the right deoxynucleotide base from among the four phosphorfluorophore-dNTP substrates. **(b)** The dATP version of the phosphorfluorophore-dNTP substrates. Human Biochemistry

The Human Genome Project

Completed in 2003, the Human Genome Project was a 13-year collaborative international, government-, and private-sponsored effort to map and sequence the entire human genome, some 3 billion base pairs distributed among the two sex chromosomes (X and Y) and 22 autosomes (chromosomes that are not sex chromosomes). A primary goal was to identify and map at least 3000 genetic **markers** (genes or other recognizable loci on the DNA), which were evenly distributed throughout the chromosomes at roughly 100-kb intervals. At the same time, determination of the entire nucleotide sequence of the human genome was undertaken. J. Craig Venter and colleagues working at Celera, a private corporation, took an alternative approach based on computer alignment of sequenced human DNA fragments. A working draft of the human genome was completed in June 2000 and published in February 2001. In reality, the human genome sequences reported in 2011 were incomplete. About 8% of human DNA is found in heterochromatin (regions of highly compacted DNA located principally near the centromeres and telomeres of chromosomes). With the advent of PacBio SMRT and Oxford Nanopore Technology (ONT) long-read sequencing technology (Sections 11.3e and f), accurate nucleotide sequence information about these regions was finally obtained and the first truly complete human genome was published in 2022. An ancillary part of the project focused on sequencing the genomes of other species (such as yeast, *Drosophila melanogaster* [the fruit fly], mice, and *Arabidopsis thaliana* [a plant]) to reveal comparative aspects of genetic and sequence organization (Table 11.1).

The Human Genome Project cost \$3 billion, or about \$1/base. Today, thanks to technological advances, any person’s genome can be sequenced for less than \$1,000. This success ushers in the exciting new era of **personalized medicine**, where genomic information can be used to make customized treatment decisions about patients. As of 2020, the Human Gene Mutation Database (HGMD) listed more than 300,000 mutations in almost 12,000 genes associated with human disease. Related developments include the Cancer Genome Atlas (information on the genomes of over 11,000 tumors from 33 of the most common cancers as of 2018), the British 100,000 Genomes Project (completed in 2018, a compilation of 100,000 genomes from around 85,000 patients ill with a rare disease or cancer), and the 1,000 Genomes Project of BGI Group (initiated in 2008 and completed in 2015, a detailed catalog of global human genetic variation). In 2018, the Earth BioGenome Project was launched,

with the goal of sequencing the DNA of the 1.5 million known species of eukaryotes. The 24 September 2021 issue of *Science* (volume 373, issue 6562) marks the 20th anniversary of the publication of a first-draft human genome sequence and reviews the legacy of this accomplishment.

Table 11.1 Completed Genome Nucleotide Sequences¹

11.1f Oxford Nanopore Technologies (ONT) Real-Time Sequencing

A record of a DNA molecule’s sequence is carried in each of its strands. It would be advantageous to have a platform that could read single-stranded DNA sequences rapidly, accurately, and reliably. One new approach is to measure the change in the electrical properties of a synthetic membrane as single strands of DNA (or RNA) are pulled through nanopores in the membrane. As a polynucleotide chain is pulled through such a nanopore, the electrical conductance of the pore is altered in subtly different ways, depending on nature of the chain’s nucleotide sequence (Figure 11.6). Readout of these electrical changes reveals the sequence of the DNA directly, without the need for expensive reagents or chemical or enzymatic reactions, as in SBS sequencing. ONT technology achieves long reads of DNA sequence, from one to

Figure 11.6 ONT sequencing. (a) In ONT sequencing, long double-stranded DNA fragments are tagged with sequencing adapters (light blue) that carry a preloaded motor protein on one or both ends (yellow). (b) This DNA construct is combined with proteins (not shown) that will tether the DNA to the nanopore and then introduced onto the sequencing flow cell. The flow cell contains a synthetic membrane studded with thousands of protein nanopores. Each tethering protein: DNA complex attaches to a nanopore. (c) The sequencing adapter inserts into the nanopore, and the motor protein unwinds the double-stranded DNA, threading a single-DNA strand through the nanopore. An applied electric current in concert with the motor protein drives the negatively charged DNA strand through the pore at a rate of about 450 bases per second. As the DNA moves through the pore, it causes disruptions to the current. These changes relate to the nature of the specific deoxynucleotide sequences passing through the pore and can be used to identify the DNA sequence. Adapted from Figure 2 in Logsdon, G. A., Vollger, M. R., and Eichler, E. E., 2020. Long-read human genome sequencing and its applications. *Nature Reviews Genetics* 21:597–614.

several hundred kb and even up to several Mb in length. Further advantages include lower cost for ONT sequencing instruments and their compact size, making them useful for sequencing studies in the field, away from sophisticated laboratories. ONT technology was instrumental in constructing the first entire nucleotide sequence of a human chromosome from end-to-end, the 155-megabasepair X chromosome. And combined PacBio SMRT-sequencing and ONT sequencing allowed the assembly of the entire 146,259,671 bp-long, telomere-to-telomere sequence of human chromosome 8.

11.1g Bioinformatics—Functional Genomics, Proteomics, and More

The growing body of information about whole genome sequences of organisms has created a new branch of science called **bioinformatics**: the study of the nature and organization of biological information. Bioinformatics includes such approaches as **functional genomics** and **proteomics**.

Functional genomics addresses global issues of gene expression, such as looking at all the genes that are activated during major metabolic shifts (as from growth under aerobic to growth under anaerobic conditions) or during embryogenesis and development of organisms. **Transcriptome** is the word used in functional genomics to define the entire set of genes expressed (as mRNAs transcribed from DNA) in a particular cell or tissue under defined conditions. Functional genomics also provides new insights into evolutionary relationships between organisms.

Proteomics is the study of all the proteins expressed by a certain cell or tissue under specified conditions. Typically, this set of proteins, the **proteome**, is revealed by running two-dimensional polyacrylamide gel electrophoresis on a cellular extract or by coupling protein separation techniques to mass spectrometric analysis.

11.2 What Sorts of Secondary Structures Can Double-Stranded DNA Molecules Adopt?

Single strands of DNA or RNA are conformationally dynamic. Unlike the constraint imposed on the conformation of polypeptides by the amide plane, no analogous constraint exists along the sugar- PO_4 backbone of polynucleotides.

11.2a Conformational Variation in Polynucleotide Strands

Polynucleotide strands are inherently flexible. Each deoxyribose-phosphate segment of the backbone has six degrees of freedom (Figure 11.7a) as a consequence of the six

successive single bonds per segment along the chain. Furanose rings of pentoses are not planar but instead adopt puckered conformations, four of which are shown in Figure 11.7b. A seventh degree of freedom per nucleotide unit arises because of free rotation about the C1'-N glycosidic bond. This freedom allows the plane of the base to rotate relative to the path of the polynucleotide strand (Figure 11.7c).

11.2b DNA Usually Occurs in the Form of Double-Stranded Helices

Fundamentally, double-stranded DNA is a regular two-chain structure with hydrogen bonds formed between opposing bases on the two chains (see Chapter 10). Such H bonding is possible only when the two chains are antiparallel. The polar sugar-phosphate backbones of the two chains are on the outside. The bases are stacked on the inside of the structure; these heterocyclic bases, as a consequence of their π -electron clouds, are hydrophobic on their flat sides. One purely hypothetical conformational possibility for a two-stranded arrangement would be a ladderlike structure (Figure 11.8a) in which the base pairs are fixed at 0.6 nm apart because this is the distance between adjacent sugars along a polynucleotide strand. Because H₂O molecules could fit into the spaces between the hydrophobic surfaces of the bases, this conformation is energetically unfavorable. This ladderlike structure converts to a double helix when given a simple right-handed twist (Figure 11.8b). Helical twisting brings the base-pair rungs of the ladder closer together, stacking them 0.34 nm apart, without affecting the sugar-sugar distance of 0.6 nm. Because this helix repeats itself approximately every 10 bp, its **pitch** is 3.4 nm. This is the major conformation of DNA in solution, and it is called **B-DNA**.

11.2c Watson-Crick Base Pairs Have Virtually Identical Dimensions

As indicated in Chapter 10, the base pairing in DNA is size complementary: Large bases (purines) pair with small bases (pyrimidines). Hydrogen bond formation between purines and pyrimidines dictates that the purine adenine pairs with the pyrimidine thymine; the purine guanine pairs with the pyrimidine cytosine. Size complementarity means that the A:T pair and G:C pair have virtually identical dimensions (Figure 11.9). Watson and Crick realized that units of such structural equivalence could serve as spatially invariant substructures to build a polymer whose exterior dimensions would be uniform along its length, regardless of the sequence of bases. That is, the pairing of smaller pyrimidines with larger purines everywhere across the double-stranded molecule allows the two polynucleotide strands to assume essentially identical helical conformations.

11.2d The DNA Double Helix Is a Stable Structure

Several factors account for the stability of the double helical structure of DNA.

H Bonds Although it has long been emphasized that the two strands of DNA are held together by H bonds formed between the complementary purines and pyrimidines, two in an A:T pair and three in a G:C pair (Figure 11.9), the H bonds between base pairs impart little net stability to the double-stranded structure compared with the separated strands in solution. When the two strands of the double helix are separated, the H bonds between base pairs are replaced by H bonds between individual bases and surrounding water molecules. Polar atoms in the sugar-phosphate backbone do form external H bonds with surrounding water molecules, but these form with separated strands as well.

Electrostatic Interactions A prominent feature of the backbone of a DNA strand is the repeating array of negatively charged phosphate groups. These arrays of negative charge along the strands repel each other so that their sugar-phosphate

Figure 11.8 (a) Double-stranded DNA as an imaginary ladderlike structure. (b) A simple right-handed twist converts the ladder to a helix.

Figure 11.9 Watson–Crick A:T and G:C base pairs. All H bonds in both base pairs are straight.

backbones are kept apart and the two strands come together through Watson–Crick base pairing. As a consequence, the negative charges are situated on the exterior surface of the double helix, such that repulsive effects are minimized. Further these charges become electrostatically shielded from one another because divalent cations, particularly Mg^{2+} , bind strongly to the anionic phosphates. Mg^{2+} ions are abundant in cells.

Van der Waals and Hydrophobic Interactions The core of the helix consists of the base pairs that stack together through π , π -electronic interactions (a form of van der Waals interaction) and hydrophobic forces. These base-pair stacking interactions range from -16 to -51 kJ/mol (expressed as the energy of interaction between adjacent base pairs), contributing significantly to the overall stabilizing energy.

A consequence of the way A:T and G:C base pairs form is that the sugars of the respective nucleotides have opposite orientations. This is why the sugar–phosphate backbones of the two chains run in opposite or “antiparallel” directions. Furthermore, the two glycosidic bonds holding the bases in each base pair are not directly across the helix from each other (Figure 11.10). Consequently, the sugar–phosphate backbones of the helix are not equally spaced along the helix axis and the grooves between them are not the same size. Instead, the intertwined chains create a **major groove** and a **minor groove** (Figure 11.10). The edges of the base pairs have a specific relationship to these grooves. The “top” edges of the base pairs (“top” as defined by placing the glycosidic bond at the bottom, as shown in Figure 11.10) are exposed along the interior surface or “floor” of the major groove; the base-pair edges nearest to the glycosidic bond form the interior surface of the minor groove. Some proteins that bind to DNA can actually recognize specific nucleotide sequences by “reading” the pattern of H-bonding possibilities presented by the edges of the bases in these grooves. Such DNA–protein interactions provide one step toward understanding how cells regulate the expression of genetic information encoded in DNA.

Figure 11.10 The major and minor grooves of B-DNA.

11.2e Double Helical Structures Can Adopt a Number of Stable Conformations

In solution, DNA ordinarily assumes the familiar structure we have been discussing: B-DNA. However, nucleic acids also occur naturally in other double-helical forms. The base-pairing arrangement remains the same, but the inherently flexible sugar—phosphate backbone adopts different conformations. Base-pair rotations are one form of conformational variation. **Helical twist** is the rotation (around the axis of the double helix) of one base pair relative to the next (Figure 11.11a). Successive base pairs in B-DNA show a mean rotation of 36° with respect to each other. **Propellor twist** involves rotation around a different axis, namely, an axis perpendicular to the helix axis (Figure 11.11b). Propellor twist allows greater overlap between successive bases along a strand of DNA and diminishes the area of contact between bases and solvent water.

11.2f A-Form DNA Is an Alternative Form of Right-Handed DNA

An alternative form of the right-handed double helix is A-DNA. A-DNA molecules differ from B-DNA molecules in a number of ways. The pitch, or distance required to complete one helical turn, is different. In B-DNA, it is 3.4 nm, whereas in A-DNA, it is 2.46 nm. One turn in A-DNA requires 11 bp to complete. Depending on local sequence, 10 to 10.6 bp define one helical turn in B-form DNA. In A-DNA, the base pairs are no longer nearly perpendicular to the helix axis but instead are tilted 19° with respect to this axis. Successive base pairs occur every 0.23 nm along

Figure 11.11 Helical twist and propellor twist in DNA. (a) Successive base pairs in B-DNA show a rotation with respect to each other. (b) Rotation in a different dimension—**propellor twist**—allows the hydrophobic surfaces of bases to overlap better. Dots represent axes perpendicular to the helix axis. The view is from the sugar–P backbone. (c) Each of the bases in a base pair shows positive propellor twist (a clockwise rotation from the horizontal, as viewed along the *N*-glycosidic bond, from the pentose C1' to the base). (Adapted from Figure 3.4 in Callandine, C. R., and Drew, H. R., 1992. *Understanding DNA: The Molecule and How It Works*. London: Academic Press.)

the axis, as opposed to 0.332 nm in B-DNA. The B-form of DNA is thus longer and thinner than the short, squat A-form, which has its base pairs displaced around, rather than centered on, the helix axis. Figure 11.12 and Table 11.2 show the relevant structural characteristics of the A- and B-forms of DNA. (Z-DNA, another form of DNA to be discussed shortly, is also depicted in Figure 11.12 and Table 11.2.) A comparison of the structural properties of A-, B-, and Z-DNA is summarized in Table 11.2.

Relatively dehydrated DNA fibers can adopt the A-conformation, and DNA may be in the A-form in dehydrated structures, such as bacterial and fungal spores. The pentose conformation in A-DNA is 3'-endo, as opposed to 2'-endo in B-DNA. Double helical DNA:RNA hybrids, which readily form between sequences that are complementary, have an A-like conformation. The 2'-OH in RNA sterically prevents double helical regions of RNA chains from adopting the B-form helical arrangement. Importantly, double-stranded regions in RNA chains often assume an A-like conformation, with their bases strongly tilted with respect to the helix axis.

11.2g Z-DNA Is a Conformational Variation in the Form of a Left-Handed Double Helix

Z-DNA was first discovered when X-ray analysis of crystals of the synthetic deoxynucleotide dCpGpCpGpCpG revealed an antiparallel double helix of unexpected conformation. The alternating pyrimidine–purine (Py–Pu) sequence of this oligonucleotide is the key to its unusual properties. The *N*-glycosyl bonds of G residues in this alternating copolymer are rotated 180° with respect to their conformation in B-DNA, so that the purine ring is in the syn rather than the anti conformation (Figure 11.13). The C residues remain in the anti form. Because the G ring is “flipped,” the C ring must also flip to maintain normal Watson–Crick base pairing. However, pyrimidine nucleosides do not readily adopt the syn conformation because it creates steric interference between the pyrimidine C-2 oxy substituent and atoms of the pentose. Because the cytosine ring does not rotate relative to the

Figure 11.12 Comparison of the A-, B-, and Z-forms of the DNA double helix. The A- and B-structures show 12 bp of DNA; the Z-structures, 6 bp. The middle Z-structure shows just one strand of a Z-DNA double helix to illustrate better the left-handed zigzag path of the polynucleotide backbones in Z-DNA. (The light blue line was added to show the imaginary zigzag path.) A-DNA: PDB id = 2D47, B-DNA: PDB id = 355D, Z-DNA: PDB id = 1DCG.

Table 11.2	Comparison of the Structural Properties of A-, B-, and Z-DNA		
	Double Helix Type		
	A	B	Z
Overall proportions	Short and broad	Longer and thinner	Elongated and slim
Rise per base pair	2.3 Å	3.32 Å ± 0.19 Å	3.8 Å
Helix packing diameter	25.5 Å	23.7 Å	18.4 Å
Helix rotation sense	Right-handed	Right-handed	Left-handed
Base pairs per helix repeat	1	1	2
Base pairs per turn of helix	~11	~10	12
Mean rotation per base pair	33.6°	35.9° ± 4.2°	−60°/2
Pitch per turn of helix	24.6 Å	33.2 Å	45.6 Å
Base-pair tilt from the perpendicular	+19°	−1.2° ± 4.1°	−9°
Base-pair mean propeller twist	+18°	+16° ± 7°	~0°
Helix axis location	Major groove	Through base pairs	Minor groove
Major groove proportions	Extremely narrow but very deep	Wide and with intermediate depth	Flattened out on helix surface
Minor groove proportions	Very broad but shallow	Narrow and with intermediate depth	Extremely narrow but very deep
Glycosyl bond conformation	anti	anti	anti at C, syn at G

Figure 11.13 Comparison of the deoxyguanosine conformation in B- and Z-DNA.

pentose, the whole C nucleoside (base and sugar) must flip 180° (Figure 11.14). It is topologically possible for the G to go syn and the C nucleoside to undergo rotation by 180° without breaking and re-forming the G:C hydrogen bonds. In other words, the B-to-Z structural transition can take place without disrupting the bonding relationships among the atoms involved.

Because alternate nucleotides assume different conformations, the repeating unit on a given strand in the Z-helix is the dinucleotide. That is, for any number of bases, *n*, along one strand, *n* – 1 dinucleotides must be considered. For example, a GpCpGpC subset of sequence along one strand is composed of *three* successive dinucleotide units: GpC, CpG, and GpC. (In A- and B-DNA, the nucleotide conformations are essentially uniform and the repeating unit is the mononucleotide.) It follows that the CpG sequence is distinct conformationally from the GpC sequence along the alternating copolymer chains in the Z-double helix. The conformational alterations going from B to Z realign the sugar–phosphate backbone along a zigzag course that has a left-handed orientation (Figure 11.12), thus the designation Z-DNA. Note that in any GpCpGp subset, the sugar–phosphates of GpC form the horizontal “zig,” while the CpG backbone segment forms the vertical “zag.” The mean rotation angle circumscribed around the helix axis is

Figure 11.14 The change in topological relationships of base pairs from B- to Z-DNA. A six-base-pair GCGCGC segment of B-DNA (1) is converted to Z-DNA (2) through rotation of the base pairs, as indicated by the curved arrows. The purine rings (green) of the deoxyguanosine nucleosides rotate via an anti to syn change in the conformation of the guanine–deoxyribose glycosidic bond; the pyrimidine rings (blue) are rotated by flipping the entire deoxycytosine nucleoside (base and deoxyribose).

–15° for a CpG step and –45° for a GpC step (giving –60° for the dinucleotide repeat). The minus sign denotes a left-handed or counterclockwise rotation about the helix axis. Z-DNA is more elongated and slimmer than B-DNA.

Cytosine Methylation and Z-DNA The Z-form can arise in sequences that are not strictly alternating Py–Pu. For example, the hexanucleotide m^5CGATm^5CG , a Py–Pu–Pu–Py–Py–Pu sequence containing two 5-methylcytosines (m^5C), crystallizes as Z-DNA. Indeed, the *in vivo* methylation of C at the 5-position is believed to favor a B-to-Z switch because, in B-DNA, these hydrophobic methyl groups would protrude into the aqueous environment of the major groove, a destabilizing influence. In Z-DNA, the same methyl groups can form a stabilizing hydrophobic patch. It is likely that the Z-conformation naturally occurs in specific regions of cellular DNA, which otherwise is predominantly in the B-form. Furthermore, because methylation is implicated in gene regulation, the occurrence of Z-DNA may affect the expression of genetic information.

11.2h The Double Helix Is Flexible

The long-range structure of B-DNA in solution is not that of a rigid, linear rod. Instead, DNA behaves as a dynamic, flexible molecule. Localized thermal fluctuations temporarily distort and deform DNA structure over short regions. Base and backbone ensembles of atoms undergo elastic motions on a time scale of nanoseconds. To some extent, these effects represent changes in rotational angles of the bonds comprising the polynucleotide backbone. These changes are also influenced by sequence-dependent variations in base-pair stacking. The consequence is that the helix bends gently. When these variations are summed over the great length of a DNA molecule, these bending influences give the double helix a roughly spherical shape, as might be expected for a long, semirigid rod undergoing apparently random coiling. It is also worth noting that, on close scrutiny, the surface of the double helix is *not* that of a totally featureless, smooth, regular “barber pole” structure. Different base sequences impart their own special signatures to the molecule by subtle influences on such factors as the groove width, the angle between the helix axis and base planes, and the mechanical rigidity. Certain regulatory proteins bind to specific DNA sequences and participate in activating or

Human Biochemistry

DNA Methylation, CpG Islands, and Epigenetics

In Chapter 10, we saw that rRNA and tRNA often contain chemically modified bases (Figure 10.22). A common form of modification is methylation. Methylation of eukaryotic DNA occurs only at cytosine residues, forming 5-methylcytosine.

5-Methylcytosine

In mammals, cytosine methylation is essential for normal embryonic development. A general rule of thumb is that **cytosine methylation** switches genes to an “off” state. Then, the information they encode is not expressed. In somatic cells (cells other than gametes), most cytosine methylation occurs at cytosine residues next to Gs, that is, within CpG dinucleotides. (Note that the complementary strand would have a 5′-CpG-3′ as well.) CpG dinucleotides are rare in mammalian genomes, appearing at just 20% of their statistically expected numbers.

However, some regions of the genome contain CpG dinucleotides at expected frequencies. Small regions of DNA (less than 500 bp or so) that contain expected amounts of CpG dinucleo-

tides are called **CpG islands** (CGIs). CGIs are G-C rich (about 65% G-C content, compared with the average 40% G-C content of mammalian genomes). The Cs in CGIs are usually unmethylated. Those that are methylated tend to lie in gene regulatory regions and shut down gene expression.

Epigenetics is the study of heritable changes in the genome that occur without a change in nucleotide sequence. Epigenetic changes are reversible and include modifications that occur in DNA (such as methylation) and in histones, the principal proteins found in chromatin, the DNA–protein complex in the eukaryotic nucleus. Epigenetic changes can influence expression of the information encoded by the genome.

Hypermethylation of CGIs in tumor suppressor genes can shut down the expression of these genes, leading to cancer.

suppressing expression of the information encoded therein. These proteins bind at unique sites due to their ability to recognize novel structural characteristics imposed on the DNA by the local nucleotide sequence.

Intercalating Agents Distort the Double Helix Aromatic macrocycles, flat hydrophobic molecules composed of fused, heterocyclic rings, such as **ethidium bromide**, **acridine orange**, and **actinomycin D** (Figure 11.15), can slip between the stacked base pairs of DNA. The base pairs move apart to accommodate these so-called **intercalating agents**, causing an unwinding of the helix to a more ladderlike structure. The deoxyribose–phosphate backbone is almost fully extended as successive base pairs are displaced 0.7 nm from one another, and the rotational angle about the helix axis between adjacent base pairs is reduced from 36° to 10°.

Dynamic Nature of the DNA Double Helix in Solution Intercalating substances insert with ease into the double helix, indicating that the van der Waals stacking interactions that they share with the bases sandwiching them are more favorable than similar interactions between the bases themselves. Furthermore, the fact that these agents slip in suggests that the double helix must momentarily unwind and present gaps for these agents to occupy. That is, the DNA double helix in solution must be represented by a set of metastable alternatives to the standard B-conformation. These alternatives constitute a flickering repertoire of dynamic structures.

11.2i Alternative Hydrogen-Bonding Interactions Give Rise to Novel DNA Structures: Cruciforms, Triplexes, and Quadruplexes

Cruciform Structures Arise from Inverted Repeats Inverted repeats (Figure 11.16) are duplex DNA sequences showing twofold symmetry (the 5′→3′ sequence is identical in both strands). **Palindromes** are words, phrases, or sentences that read the same

Figure 11.15 The structures of ethidium bromide, acridine orange, and actinomycin D, three intercalating agents, and their effects on DNA structure.

Figure 11.16 Self-complementary inverted repeats can rearrange to form hydrogen-bonded cruciform stem-loop structures.

backward or forward, such as “radar,” “sex at noon taxes,” “Madam, I’m Adam,” and “a man, a plan, a canal, Panama.” Inverted repeats are sometimes referred to as palindromes (despite the inaccuracy of this description). Inverted repeats have the potential to adopt **cruciform** (meaning “cross-shaped”) structures if the normal interstrand base pairing is replaced by intrastrand pairing. In effect, each strand forms a hairpin structure through alignment and pairing of the self-complementary sequences along the strand. Cruciforms are never as stable as normal DNA duplexes because an unpaired segment must exist in the loop region. Cruciforms potentially create novel structures that can serve as distinctive recognition sites for specific DNA-binding proteins.

Hoogsteen Base Pairs and DNA Multiplexes The A:T and G:C base pairs first seen by Watson (Figure 11.9) are the canonical building blocks for DNA structures. However, Karst Hoogsteen found that adenine and thymine do not pair in this way when crystallized from aqueous solution. Instead, they form two H bonds in a different arrangement (Figure 11.17). Further, Hoogsteen observed that in mildly acidic solutions, guanine and cytosine form base pairs different from Watson–Crick G:C base pairs. These Hoogsteen base pairs depend upon protonation of cytosine N-3 (Figure 11.17) and have only two H bonds, not three. In both A:T and G:C Hoogsteen base pairs, the purine N-7 atom is an H-bond acceptor. The functional groups of adenine and guanine that participate in Watson–Crick H bonds remain accessible in Hoogsteen base pairs. Thus, base triplets can form, as shown in Figure 11.18, giving rise to TAT and C⁺GC triplets, where each purine interacts with one of its pyrimidine partners through Hoogsteen base pairing and the other through Watson–Crick base pairing.

Figure 11.17 Hoogsteen base pairs: A:T (left) and C⁺:G (right).

Figure 11.18 Base triplets formed when a purine interacts with one pyrimidine by Hoogsteen base-pairing and another by Watson–Crick base pairing.

11.3 Can the Secondary Structure of DNA Be Denatured and Renatured?

When duplex DNA molecules are subjected to conditions of pH, temperature, or ionic strength that disrupt base-pairing interactions, the strands are no longer held together. That is, the double helix is **denatured**, and the strands separate as individual random coils. If temperature is the denaturing agent, the double helix is said to *melt*.

11.3a Thermal Denaturation of DNA Can Be Observed by Changes in UV Absorbance

DNA denaturation can be followed spectrophotometrically because the relative absorbance of the DNA solution at 260 nm increases as much as 40% as the bases unstack. This absorbance increase, or **hyperchromic shift**, is due to the fact that the aromatic bases in DNA interact via their π -electron clouds when stacked together in the double helix. Because the UV absorbance of the bases is a consequence of π -electron transitions, and because the potential for these transitions is diminished when the bases stack, the bases in duplex DNA absorb less 260-nm radiation than expected for their numbers. Unstacking alleviates this suppression of UV absorbance. The rise in absorbance coincides with strand separation, and the midpoint of the absorbance increase is termed the **melting temperature**, T_m (Figure 11.21). DNAs differ in their T_m values because they differ in relative G + C content. The higher the G + C content of a DNA, the higher its melting temperature because G:C pairs have higher base-stacking energies than A:T pairs. Also, T_m is dependent on the ionic strength of the solution; the lower the ionic strength, the lower the melting temperature. Because cations suppress the electrostatic repulsion between the negatively charged phosphate groups in the complementary strands of the double helix, the double-stranded form of DNA is more stable in dilute salt solutions. DNA in pure water melts even at room temperature.

11.3b pH Extremes or Strong H-Bonding Solutes also Denature DNA Duplexes

At pH values greater than 10, the bases of DNA lose protons, which destroys their base-pairing potential, thus denaturing the DNA duplex. Extensive addition of protons to the bases below pH 2.3 also disrupts base pairing. Alkali is the preferred denaturant because, unlike acid, it does not hydrolyze the glycosidic bonds linking purine bases to the sugar-phosphate backbone. Small solutes that readily form H bonds can also denature duplex DNA at temperatures below T_m . If present in sufficiently high concentrations, such small solutes will form H bonds with the bases, thereby disrupting H-bonding interactions between the base pairs. Examples include formamide and urea.

11.3c Single-Stranded DNA Can Renature to Form DNA Duplexes

Denatured DNA will **renature** to re-form the duplex structure if the denaturing conditions are removed (that is, if the solution is cooled, the pH is returned to neutrality, or the denaturants are diluted out). Renaturation requires reassociation of the DNA

Figure 11.21 Heat denaturation of DNA from various sources, so-called melting curves. (Adapted from Marmur, J., 1959. Heterogeneity in deoxyribonucleic acids. *Nature* **183**:1427–1429.)

A Deeper Look

The Buoyant Density of DNA

Density gradient ultracentrifugation is a variant of the basic technique of ultracentrifugation (discussed in Chapter 5). The densities of DNAs are about the same as those of concentrated solutions of cesium chloride, CsCl (1.6 to 1.8 g/mL). Centrifugation of CsCl solutions at very high rotational speeds, where the centrifugal force becomes 10^5 times stronger than the force of gravity, causes the formation of a density gradient within the solution. This gradient is the result of a balance that is established between the sedimentation of the salt ions toward the bottom of the tube and their diffusion upward toward regions of lower concentration. If DNA is present in the centrifuged CsCl solution, it moves to a position of equilibrium in the gradient equivalent to its buoyant density (as shown in the figure). For this reason, this technique is also called **isopycnic centrifugation**.

Cesium chloride centrifugation is an excellent means of removing RNA and proteins in the purification of DNA. The density of dsDNA is typically slightly greater than 1.7 g/cm^3 , whereas the density of RNA is more than 1.8 g/cm^3 . Proteins have densities less than 1.3 g/cm^3 . In CsCl solutions of appropriate density, the DNA bands near the center of the tube, RNA pellets to the bottom, and the proteins float near the top. Single-stranded DNA is denser than double helical DNA. The irregular structure of randomly coiled ssDNA allows the atoms to pack together through van der Waals interactions. These interactions compact the molecule into a smaller volume than that occupied by a hydrogen-bonded double helix.

The net movement of solute particles in an ultracentrifuge is the result of two processes: diffusion (from regions of higher concentration to regions of lower concentration) and sedimentation due to centrifugal force (in the direction away from the axis of rotation). In general, diffusion rates for molecules are inversely proportional to their molecular weight—larger molecules diffuse more slowly than smaller ones. On the other hand, sedimentation rates increase with increasing molecular weight. A macromolecular species that has reached its position of density equilibrium in isopycnic centrifugation has formed a concentrated band of material.

Essentially three effects are influencing the movement of the molecules in creating this concentration zone: (1) diffusion away to regions of lower concentration, (2) sedimentation of molecules situated at positions of slightly lower solution density in the density gradient, and (3) flotation (buoyancy or “reverse sedimentation”) of molecules that have reached positions of slightly greater solution density in the gradient. The consequence of the physics of these effects is that, at equilibrium, *the width of the concentration band established by the macromolecular species is inversely proportional to the square root of its molecular weight*. That is, a population of large molecules will form a concentration band that is narrower than the band formed by a population of small molecules. For example, the bandwidth formed by dsDNA will be less than the bandwidth formed by the same DNA when dissociated into ssDNA.

strands into a double helix, a process termed **renannealing**. For this to occur, the strands must realign themselves so that their complementary bases are once again in register and the helix can be zippered up (Figure 11.22). Renaturation is dependent on both DNA concentration and time. Many of the realignments are imperfect, and thus the strands must dissociate again to allow for proper pairings to be formed. The process occurs more quickly if the temperature is warm enough to promote diffusion of the large DNA molecules but not so warm as to cause melting.

11.3d The Rate of DNA Renaturation Is an Index of DNA Sequence Complexity

The renaturation rate of DNA is an excellent indicator of the sequence complexity of DNA. For example, the DNA of bacteriophage T4 contains 2×10^5 base pairs; an *Escherichia coli* chromosome contains more than 10 times as much (4.64×10^6 base pairs). *E. coli* DNA is considerably more complex in that it encodes more information. Expressed in another way, for any fixed amount of single-stranded DNA (in grams), the nucleotide sequences represented in an *E. coli* sample will show greater sequence

Figure 11.22 Steps in the thermal denaturation and renaturation of DNA. The nucleation phase of the reaction is a second-order process depending on sequence alignment of the two strands (1). This process takes place slowly because it takes time for complementary sequences to encounter one another in solution and then align themselves in register. Once the sequences are aligned, the strands zipper up quickly (2).

variation than those in an equal weight of phage T4 DNA. Thus, it will take longer for the *E. coli* DNA strands to find their complementary partners and reanneal. Because the rate of DNA duplex formation depends on complementary DNA sequences encountering one another and beginning the process of sequence alignment and reannealing, the time necessary for reconstituting double-stranded DNA molecules is an excellent index of the degree of sequence complementarity in a DNA sample.

11.3e Nucleic Acid Hybridization: Different DNA Strands of Similar Sequence Can Form Hybrid Duplexes

If DNA from two different species are mixed, denatured, and allowed to cool slowly so that reannealing can occur, **hybrid duplexes** may form, provided the DNA from one species is similar in nucleotide sequence to the DNA of the other. The degree of hybridization is a measure of the sequence similarity, or *relatedness*, between the two species. Depending on the conditions of the experiment, about 25% of the DNA from a human forms hybrids with mouse DNA, implying that some of the nucleotide sequences (genes) in humans are very similar to those in mice (Figure 11.23). Mixed RNA:DNA hybrids can be created in vitro if single-stranded DNA is allowed to anneal with RNA copies of itself, such as those formed when genes are transcribed into mRNA molecules.

Nucleic acid hybridization is a commonly employed procedure in molecular biology. First, it can reveal evolutionary relationships. Second, it gives researchers the power to identify specific genes selectively against a vast background of irrelevant genetic material: An appropriately labeled oligonucleotide or polynucleotide, referred to as a **probe**, is constructed so that its sequence is complementary to a target gene. The probe specifically base pairs with the target gene, allowing identification and subsequent isolation of the gene. Also, the quantitative expression of genes (in terms of the amount of mRNA synthesized) can be assayed by hybridization experiments.

Figure 11.23 Solutions of human DNA (red) and mouse DNA (blue) are mixed and denatured, and the single strands are allowed to reanneal. About 25% of the human DNA strands form hybrid duplexes (one red and one blue strand) with mouse DNA.

11.4 How Does DNA Adopt Structures of Higher Complexity?

Not all DNA molecules are linear; many DNA molecules are circular. Most, but not all, bacterial chromosomes are covalently closed, circular DNA duplexes, as are most plasmid DNAs. **Plasmids** are naturally occurring, self-replicating, extrachromosomal DNA molecules found in bacteria; plasmids carry genes specifying novel metabolic capacities advantageous to the host bacterium. Various animal virus DNAs are circular as well. DNA can adopt regular structures of higher complexity in several ways.

11.4a Supercoils Are One Kind of Structural Complexity in DNA

In duplex DNA, the two strands are wound about each other once every 10 bp or so, that is, once every turn of the helix. Double-stranded circular DNA (or linear DNA duplexes whose ends are not free to rotate) form **supercoils** if the strands are underwound (*negatively supercoiled*) or overwound (*positively supercoiled*) (Figure 11.24). Underwound duplex DNA has fewer than the normal number of turns, whereas overwound DNA has more. DNA supercoiling is analogous to twisting or untwisting a two-stranded rope so that it is torsionally stressed. Negative supercoiling introduces a torsional stress that favors unwinding of the right-handed B-DNA double helix, whereas positive supercoiling overwinds such a helix. Both forms of supercoiling compact the DNA so that it sediments faster upon ultracentrifugation or migrates more rapidly in an electrophoretic gel in comparison to **relaxed DNA** (DNA that is not supercoiled). Cellular DNA is almost always negatively supercoiled (underwound).

11.4b Supercoiled DNA Is Defined by Its Linking Number

The basic parameter characterizing supercoiled DNA is the **linking number** (L). This is the number of times the two strands are intertwined, and provided both strands remain covalently intact, L cannot change. In a relaxed circular DNA duplex of 400 bp, L is 40 (assuming 10 bp per turn in B-DNA). The linking number for relaxed DNA is usually taken as the reference parameter and is written as L_0 . L can be equated to the **twist** (T) and **writhe** (W) of the duplex, where twist is the number of helical turns and writhe is the number of supercoils:

$$L = T + W$$

Figure 11.24 Toroidal and interwound varieties of supercoiling. **(a)** The DNA is coiled in a spiral fashion about an imaginary toroid (yellow circle). **(b)** The DNA interwinds and wraps about itself. **(c)** Supercoils in long, linear DNA arranged into loops whose ends are restrained—a model for chromosomal DNA. (Adapted from Figures 6.2 and 6.3 in Callandine, C. R., and Drew, H. R., 2004. *Understanding DNA: The Molecule and How It Works*, 3rd ed. London: Academic Press.)

Figure 11.25 Supercoil topology for a simple circular tube with a single stripe along it. (Adapted from Figures 6.4 and 6.5 in Callandine, C. R., and Drew, H. R., 2004. *Understanding DNA: The Molecule and How It Works*, 3rd ed. London: Academic Press.)

Figure 11.25 shows the values of T and W for a simple striped circular tube in various supercoiled forms. In any closed, circular DNA duplex that is relaxed, $W = 0$. A relaxed circular DNA of 400 bp has 40 helical turns, $T = L = 40$. This linking number can be changed only by breaking one or both strands of the DNA, winding them tighter or looser, and rejoining the ends. Enzymes capable of carrying out such reactions are called **topoisomerases** because they change the topological state of DNA. Topoisomerases fall into two basic classes: I and II. Topoisomerases of the I type cut one strand of a DNA double helix, pass the other strand through, and then rejoin the cut ends. Topoisomerase II enzymes cut both strands of a dsDNA, pass a region of the DNA duplex between the cut ends, and then rejoin the ends (Figure 11.26). Topoisomerases are important players in DNA replication (see Chapter 28).

11.4c Enzymes Can Add or Remove Supercoils

The bacterial enzyme **DNA gyrase** is a topoisomerase that introduces negative supercoils into DNA in the manner shown in Figure 11.26. Suppose DNA gyrase puts four negative supercoils into the 400-bp circular duplex, then $W = -4$, T remains the same, and $L = 36$ (Figure 11.27). In actuality, the negative supercoils cause a torsional stress on the molecule, so T tends to decrease; that is, the helix becomes a bit unwound, so base pairs are separated. The extreme would be that T would decrease by 4 and the supercoiling would be removed ($T = 36$, $L = 36$, and $W = 0$). That is, negative supercoiling has the potential to cause localized unwinding of the DNA double helix so that single-stranded

Figure 11.26 A model for the action of bacterial DNA gyrase (topoisomerase II). The A-subunits cut the DNA duplex (1) and then hold onto the cut ends (2). Conformational changes in the enzyme allow an intact region of the DNA duplex to pass between the cut ends. The cut ends are religated (3), and the covalently complete DNA duplex is released from the enzyme. The circular DNA now contains two negative supercoils (4).

Figure 11.27 A 400-bp circular DNA molecule in different topological states: (a) relaxed, (b) negative supercoils distributed over the entire length, and (c) negative supercoils creating a localized single-stranded region.

regions (or bubbles) are created (Figure 11.27). Usually, the natural situation is a compromise in which the negative value of W is reduced, T decreases slightly, and these changes are distributed over the length of the circular duplex so that no localized unwinding of the helix ensues. Nevertheless, negative supercoiling makes it easier to separate the DNA strands and access the information encoded by the nucleotide sequence.

Superhelix Density The difference between the linking number of a DNA and the linking number of its relaxed form is $\Delta L = (L - L_0)$. In our example with four negative supercoils, $\Delta L = -4$. The **superhelix density** or **specific linking difference** is defined as $\Delta L/L_0$ and is sometimes termed *sigma*, σ . For our example, $\sigma = -4/40$, or -0.1 . As a ratio, σ is a measure of supercoiling that is independent of length. Its sign reflects whether the supercoiling tends to unwind (*negative* σ) or overwind (*positive* σ) the helix. In other words, the superhelix density states the number of supercoils per 10 bp, which also is the same as the number of supercoils per B-DNA repeat. Circular DNA isolated from natural sources is always found in the underwound, negatively supercoiled state.

Toroidal Supercoiled DNA Negatively supercoiled DNA can arrange into a toroidal state (Figure 11.28). The toroidal state of negatively supercoiled DNA is stabilized by wrapping around proteins that serve as spools for the DNA “ribbon.” This toroidal conformation of DNA is found in protein–DNA interactions that are the basis of phenomena as diverse as chromosome structure (see Figure 11.31) and gene expression.

11.5 | What Is the Structure of Eukaryotic Chromosomes?

A typical human cell is 20 μm in diameter. Its genetic material consists of 23 pairs of dsDNA molecules in the form of **chromosomes**, the average length of which is 3×10^9 bp/23 or 1.3×10^8 nucleotide pairs. At 0.34 nm/bp in B-DNA, this represents a DNA molecule 5 cm long. Together, these 46 dsDNA molecules amount to more than 2 m of DNA that must be packaged into a nucleus perhaps 10 μm in diameter! Clearly, the DNA must be condensed by a factor of more than 10^5 . The mechanisms by which this condensation is achieved are not completely understood at the present time, but it is clear that the first stage of this condensation is accomplished by neatly wrapping the DNA around protein spools called **nucleosomes**.

Figure 11.28 Supercoiled DNA in a toroidal form wraps readily around protein spools. A twisted segment of linear DNA with two negative supercoils (a) can collapse into a toroidal conformation if its ends are brought closer together (b). Wrapping the DNA toroid around a protein “spool” stabilizes this conformation (c). (Adapted from Figure 6.6 in Callandine, C. R., and Drew, H. R., 2004. *Understanding DNA: The Molecule and How It Works*, 3rd ed. London: Academic Press.)

11.5a Nucleosomes Are the Fundamental Structural Unit in Chromatin

The DNA in a eukaryotic cell nucleus during the interphase between cell divisions exists as a nucleoprotein complex called **chromatin**. The proteins of chromatin fall into two classes: **histones** and **nonhistone chromosomal proteins**. Histones are abundant and play an important role in chromatin structure. In contrast, the nonhistone class is defined by a great variety of different proteins, all of which are involved in genetic regulation; typically, there are only a few molecules of each per cell. Five distinct histones are known: **H1**, **H2A**, **H2B**, **H3**, and **H4** (Table 11.3). All five are relatively small, positively charged, arginine- or lysine-rich proteins that interact via ionic bonds with the negatively charged phosphate groups on the polynucleotide backbone. Pairs of histones H2A, H2B, H3, and H4 aggregate to form octameric core structures, and the DNA helix is wound about these core octamers, creating **nucleosomes**.

If chromatin is treated with mild detergent and prepared for viewing in the electron microscope, the nucleosomes are evident as “beads on a string,” dsDNA being the string. The structure of the histone octamer core wrapped with DNA has been solved by T. J. Richmond and collaborators (Figure 11.29). The core octamer has surface landmarks that guide the course of the DNA; 147 bp of B-DNA in a flat, left-handed superhelical conformation make 1.6 turns around the histone core (Figure 11.29), which itself is a protein superhelix consisting of a spiral array of the four histone dimers. Histone H1, a three-domain protein, organizes an additional 29 to 43 bp of DNA and links consecutive nucleosomes. Each complete nucleosome unit contains 176 to 190 bp of DNA. The N-terminal tails of histones H3 and H4 are accessible on the surface of the nucleosome. Lysine and serine residues in these tails can be covalently modified in myriad ways (lysines may be acetylated, methylated, or ubiquitinated; serines may be phosphorylated). These modifications play an important role in chromatin dynamics and gene expression. A single nucleosome and its associated H1 linker is referred to as a **chromatosome**.

Table 11.3 Properties of Histones

Histone	Ratio of Lysine to Arginine	Size (kD)	Copies per Nucleosome
H1	59/3	21.2	1 (not in core)
H2A	13/13	14.1	2
H2B	20/8	13.1	2
H3	13/17	15.1	2
H4	11/14	11.4	2

The four types of core histones are shown as different colors. **(a)** View down the axis of the nucleosome; **(b)** View perpendicular to the axis (PDB id = 1AOI). (Adapted from Luger, K., et al., 1997. Crystal structure of the nucleosome core particle at 2.8 Å resolution. *Nature* **389**:251–260. Photos courtesy of T. J. Richmond, ETH-Hönggerberg, Zurich, Switzerland.)

11.5b Higher-Order Structural Organization of Chromatin Gives Rise to Chromosomes

The DNA double helix has a diameter of about 2 nm. And, as indicated earlier, the total length of the 46 DNA molecules in a human cell is roughly 2 meters. And all this DNA must be contained within the nucleus, which is around 10 μm in diameter. Thus, the total length of human DNA is over 5 orders of magnitude greater than the diameter of the organelle which contains it. And within this small volume, the DNA must remain accessible so that the processes of gene expression and DNA replication are possible. The first stage in DNA compaction is wrapping it around nucleosomes. The mechanisms involved in compacting it further and the structures that result, including the overall structure of chromosomes, are under intensive study.

It is important to keep in mind that chromosomes are structurally dynamic. In cells undergoing mitosis (cell division), the chromatin of each chromosome has been duplicated and highly condensed in preparation for distribution to the two daughter cells. In the nuclei of interphase cells (cells that are not undergoing mitosis), the chromatin of each chromosome is dispersed, and despite its flexibility and limited compaction, it is not entangled with the chromatin of other chromosomes. Instead, individual chromosomes occupy distinct **chromosome territories** within the nucleus (Figure 11.30a). At a

Figure 11.30 Chromosome structural dynamics. Each chromosome occupies its own discrete territory within the nucleus. Individual chromosomes are shown in different colors. (Adapted from Figure 1 Kempfer, R., and Pombo, A., 2020. Methods for mapping 3D chromosome architecture. *Nature Reviews Genetics* 21:207–226.) (b) SMC protein architecture. SMC proteins range from 115 to 165 kD in size. (b) SMC protein function. SMC proteins are reminiscent of motor proteins. Illustrated in (c) is a condensation of DNA into a coiled arrangement through SMC2/SMC4-mediated interactions.

smaller scale, chromosomal chromatin in interphase nuclei is organized into topologically associated domains (TADs) that have a median size of about 200 kb. Human cells have about 10,000 such TADs. TADs seem to define replication units as well as units of coordinate gene transcription.

11.5c SMC Proteins Establish Chromosome Organization and Mediate Chromosome Dynamics

Two different multi-subunit complexes, **condensin** and **cohesin**, mediate the changes in chromosome compaction that take place over the course of the cell cycle. **SMC proteins** provide two of the five subunits found in both condensin and cohesin. **SMC** stands for structural maintenance of chromosomes. SMC proteins are members of the nonhistone chromosomal protein class. SMC proteins form a large superfamily of ATPases involved in higher-order chromosome organization and dynamics. SMC protein representatives are found in all forms of life—archaea, bacteria, and eukaryotes. Chromosomal dynamics includes chromosome condensation, sister chromatid cohesion, genetic recombination, and DNA repair, as well as other phenomena. SMC proteins have a characteristic five-domain organization, consisting of an N-terminal globular ATP-binding domain, a rodlike dimerization domain involved in coiled coil formation, a flexible hinge region, another rodlike and coiled coil-forming region, and finally a C-terminal globular domain termed DA for its DNA-binding and ATPase abilities (Figure 11.30b). Five subgroups of SMC proteins are found in eukaryotes, and functional SMC proteins are heterodimers. SMC2/SMC4 heterodimers are essential for chromatin condensation as part of condensin complexes; SMC1/SMC3 heterodimers act in sister chromatid cohesion as part of cohesin complexes. SMC proteins form V-shaped heterodimers that bind to DNA through their DA domains and mediate chromosomal dynamics in an ATP-dependent manner. The flexible hinge region of each SMC subunit is located at the point of the V, and hinge-bending motions allow the DNA-binding parts of the two globular heads to move closer together, compacting the DNA into a higher-order structure (Figure 11.30c).

The degree of chromosome folding is modulated as cells progress through the cell cycle. During mitosis, condensin translocates along the DNA double helix and uses ATP energy to extrude loops of DNA. By this action, condensins fold chromosomes into the compact helical loop arrays that characterize mitotic chromosomes. In interphase, the cohesin complex generates loops and the topologically associating domains discussed above. A separate cohesin-mediated process drives segregation of transcriptionally active chromatin from inactive chromatin.

11.6 | How Can Nucleic Acids Be Synthesized Chemically?

Laboratory synthesis of nucleic acids frees researchers from a dependence on naturally occurring sequences for structural and functional studies. Laboratory synthesis of oligonucleotide chains of defined sequence presents some of the same problems encountered in chemical synthesis of polypeptides (see Chapter 5). First, functional groups on the monomeric units (in this case, bases) are reactive under conditions of polymerization and therefore must be protected by blocking agents. Second, to generate the desired sequence, a phosphodiester bridge must be formed between the 3'-O of one nucleotide (B) and the 5'-O of the preceding one (A) in a way that precludes the unwanted bridging of the 3'-O of A with the 5'-O of B. Finally, recoveries at each step must be high so that overall yields in the multistep process are acceptable. As in peptide synthesis (see Chapter 5), orthogonal *solid-phase methods* are used to overcome some of these problems. Commercially available automated instruments, called **DNA synthesizers** or “gene machines,” are capable of carrying out the synthesis of oligonucleotides of 150 bases or more.

11.6a Phosphoramidite Chemistry Is Used to Form Oligonucleotides from Nucleotides

Phosphoramidite chemistry is currently the accepted method of oligonucleotide synthesis. The general strategy involves the sequential addition of nucleotide units as *nucleoside phosphoramidite* derivatives to a nucleoside covalently attached to the insoluble resin. Excess reagents, starting materials, and side products are removed after each step by filtration. After the desired oligonucleotide has been formed, it is freed of all blocking groups, hydrolyzed from the resin, and purified by gel electrophoresis. The four-step cycle is shown in Figure 11.31. Chemical synthesis takes place in the 3'→5' direction (the reverse of the biological polymerization direction).

11.6b Genes and Even Chromosomes Can Be Synthesized Chemically

Individual single-stranded DNA oligonucleotides (100–200 bp in size) synthesized through phosphoramidite chemistry can be assembled to form completely synthetic double-stranded DNA. Typically, successive oligonucleotides are designed to contain overlapping sequences that encode opposing strands of the desired DNA duplex.

Figure 11.31 Solid-phase oligonucleotide synthesis. The four-step cycle starts with the first base in nucleoside form attached by its 3'-OH group to an insoluble support. Its 5'-OH is blocked with a dimethoxytrityl (DMTr) group (a). If the base has reactive $-NH_2$ functions, as in A, G, or C, then blocking groups such as *N*-benzoyl or *N*-isobutyryl chloride are used to prevent their reaction (b). In step 1, the DMTr protecting group is removed by trichloroacetic acid treatment. Step 2 is the coupling step: The second base is added in the form of a nucleoside phosphoramidite derivative whose 5'-OH bears a DMTr blocking group so it cannot polymerize with itself (c).

(c)

Figure 11.31 continued In step 2, the presence of a weak acid, such as tetrazole, activates the phosphoramidite, and it rapidly reacts with the free 5'-OH of N-1, forming a dinucleotide linked by a phosphite group. Unreacted free 5'-OHs of N-1 are blocked from further participation in the polymerization process by acetylation with acetic anhydride in step 3, referred to as *capping*. In step 4, the phosphite linkage between N-1 and N-2 is oxidized by aqueous iodine (I_2) to form the desired more stable phosphate group. Subsequent cycles add successive residues to the resin-immobilized chain. When the chain is complete, it is cleaved from the support with NH_4OH , which also removes the *N*-benzoyl- and *N*-isobutyryl-protecting groups from the amino functions on the A, G, and C residues. Phosphoramidite chemistry for oligonucleotide synthesis has been miniaturized through the development of photo-labile or acid-sensitive blocking agents. Oligonucleotides up to 200 bases in length can be synthesized as microarrays on small chips, using inkjet printing to deliver microdroplets of phosphoramidite substrates and lasers (or electrogenerated pH changes) to trigger removal of blocking groups during cycles of nucleotide addition (see Figure 12.12).

When assembled together during the gene synthesis process, double-stranded DNA molecules up to 2 kbp in length are formed. At this point, in order to make gene- and chromosome-sized synthetic DNA constructs capable of encoding metabolic pathways or genomes requires some *in vivo* system, like yeast.

To date, such methods have achieved the complete synthesis of an entire yeast chromosome, entire bacterial genomes, and even synthetic human chromosomes (though strictly speaking, it was only the DNA in these structures that was synthesized, not the complete DNA:protein complex that a chromosome is). Such technology is referred to as **DNA-write**, in counterpoint to the results of DNA sequencing studies, which can

aptly be termed **DNA-read**. The power of DNA-write is found in the realization that any desired nucleotide sequence can be constructed. Thus, creating new DNA molecules in which new mutations have been introduced, deleterious or unwanted sequences have been omitted, novel gene products such as proteins or RNAs are encoded or recoded, are all easily performed.

DNA is analogous to software. The information encoded in a genome is a program for the operation of an organism; indeed, it defines an organism. **DNA as code** in conjunction with DNA-write has opened the door to engineering new biological parts, devices, systems, and even organisms with features that heretofore never existed in nature.

DNA-write also opens the door to exploiting the remarkable stability and longevity of **DNA as a data storage medium**. The raw storage capacity of the four-base DNA information system is staggering compared with even the most advanced electronic or magnetic storage systems. It is theoretically possible to store an exabyte (10^{18} bytes; 1000 gigabytes) of information, if it were coded into DNA, in the volume of a grain of sand. (An exabyte is roughly equivalent to 200 million DVDs). Equally important, this information can be subsequently retrieved from the DNA archive and used to recreate its contents in more conventional binary forms appropriate for computer use. A disadvantage of conventional digital data-archiving systems is that they degrade and must be renewed every decade or so. However, under appropriate conditions, DNA will last for thousands of years, preserving the information encoded in it for posterity.

11.7 | What Are the Secondary and Tertiary Structures of RNA?

RNA molecules (see Chapter 10) are typically single stranded. The course of a single-stranded RNA in three-dimensional space conceivably would have six degrees of freedom per nucleotide, represented by rotation about each of the six single bonds along the sugar-phosphate backbone per nucleotide unit. (Rotation about the β -glycosidic bond creates a seventh degree of freedom in terms of the total conformational possibilities at each nucleotide.) Compare this situation with DNA, whose separated strands would obviously enjoy the same degrees of freedom. However, the double-stranded nature of DNA imposes great constraint on its conformational possibilities. Compared with dsDNA, an RNA molecule has a much greater number of conformational possibilities. Intramolecular interactions and other stabilizing influences limit these possibilities, but the higher-order structure of RNA is both specific and dynamic, bringing with it the kinds of functional possibilities once thought possible only in proteins. It turns out that cellular RNA molecules are far more versatile than DNA. In analogy with the protein structures dictated by amino acid sequence, RNA structures are determined by nucleotide sequence. The intricate three-dimensional architectures they adopt and the conformational dynamics displayed by such architectures endow RNAs with functional abilities, such as ligand binding and even catalysis. The functional complexity of RNA is the reason why RNA is so admirably suited for its role in a wide variety of biological processes.

RNA molecules are rich in double-stranded regions that form when complementary sequences within the chain come together and join via **intrastrand base-pairing**. These interactions create hairpin **stem-loop structures**, in which the base-paired regions form the stem and the unpaired regions between base pairs are the loop, as in Figures 11.32 and 11.33. Paired regions of RNA cannot form B-DNA-type double helices because the RNA 2'-OH groups are a steric hindrance to this conformation. Instead, these paired regions adopt a conformation similar to the A-form of DNA, having about 11 bp per turn, with the bases strongly tilted from the plane perpendicular to the helix axis (see Figure 11.12). A-form double helices are the most prominent secondary structural elements in RNA. Both tRNA and rRNA have large amounts of A-form double helix. In addition, a number of defined structural motifs recur within the loops of stem-loop structures, such as **U-turns** (a loop motif of consensus sequence UNRN, where N is any nucleotide and R is a purine) and **tetraloops** (another class of four-nucleotide loops found at the termini of stem-loop structures). Stems of stem-loop structures may also

Figure 11.32 Bulges and loops formed in RNA when aligned sequences are not fully complementary. (Adapted from Appendix Figure 1 in Gesteland, R. F., Cech, T. R., and Atkins, J. F., eds. *The RNA World*, 2nd ed. New York: Cold Spring Harbor Press.)

Figure 11.33 Junctions and coaxial stacking in RNA. Stem junctions (or multibranched loops) are another type of RNA secondary structure. Coaxial stacking of stems or stem-loops (as in stacking of stem 1 on stem-loop 4) is a tertiary structural feature found in many RNAs. (Adapted from Figure 1 in Tyagi, R., and Matthews, D. H., 2007. Predicting coaxial stacking in multibranch loops. *RNA* 13:1–13.)

have **bulges** (or **internal loops**) where the RNA strand is forced into a short single-stranded loop because one or more bases along one strand in an RNA double helix finds no base-pairing partners (Figure 11.32). Regions where several stem-loop structures meet are termed **junctions** (Figure 11.33). Stems, loops, bulges, and junctions are the four basic secondary structural elements in RNA.

The single-stranded loops in RNA stem-loops create base-pairing opportunities between distant, complementary, single-stranded loop regions. These interactions, mostly based on Watson–Crick base pairing, lead to tertiary structure in RNA. Other tertiary structural motifs arise from **coaxial stacking**, **pseudoknot formation**, and **ribose zippers**. In coaxial stacking, the blunt, nonloop ends of stem-loops situated next to one another in the RNA sequence stack upon each other to create an uninterrupted stack of base pairs (Figure 11.33). A good example of coaxial stacking is found in the tertiary structure of tRNAs, where the acceptor end of the L-shaped tRNA is formed by coaxial stacking of the acceptor stem on the T Ψ C stem-loop and the anticodon end is formed by coaxial stacking of the dihydrouracil stem-loop on the anticodon stem-loop

(Figures 11.35 and 11.37). Pseudoknots occur when bases in the loops of stem-loop structures form a short double helix by base pairing with nearby single-stranded regions in the RNA (Figure 11.34). Ribose zippers are found when two antiparallel, single-stranded regions of RNA align as an H-bonded network forms between the 2'-OH groups of the respective strands, the O at the 2'-OH position of one strand serving as the H-bond acceptor, while the H on the 2'-OH of the other strand is the H-bond donor. A full catalog of RNA secondary and tertiary structural motifs, including the ribose zippers and other RNA structures mentioned here, can be found in the NDB (Nucleic Acid Database) at <http://ndbserver.rutgers.edu/>. Predicting the three-dimensional structure of an RNA molecule is more challenging than predicting the structure of a protein. Machine-learning computer algorithms are having some success in meeting this challenge.

11.7a Transfer RNA Adopts Higher-Order Structure Through Intrastrand Base Pairing

In tRNA molecules, which contain 73 to 94 nucleotides in a single chain, a majority of the bases are hydrogen bonded to one another. Figure 11.35 shows the structure that typifies tRNAs. *Hairpin turns* bring complementary stretches of bases in the chain into contact so that double helical regions form, creating stem-loop secondary structures. Because of the arrangement of the complementary stretches along the chain, the overall pattern of base pairing can be represented as a *cloverleaf*. Each cloverleaf consists of four base-paired segments—three loops and the stem where the 3'- and 5'-ends of the molecule meet. These four segments are designated the *acceptor stem*, the *D loop*, the *anticodon loop*, and the *T ψ C loop* (the latter two are U-turn motifs).

tRNA Secondary Structure The *acceptor stem* is where the amino acid is linked to form the aminoacyl-tRNA derivative, which serves as the amino acid-donating species in protein synthesis; this is the physiological role of tRNA. The carboxyl group of an

Figure 11.34 RNA pseudoknots are formed when a single-stranded region of RNA folds to base-pair with a hairpin loop. Loops L1 and L2, as shown on the sequence representation of human telomerase RNA (hTR) on the left, form a pseudoknot. The three-dimensional structure of an hTR pseudoknot is shown on the right (PDB id = 1YMO). (Adapted from Figure 2 in Staple, D. W., and Butcher, S. E., 2005. Pseudoknots: RNA structures with diverse functions. *PLoS Biology* 3:e213.)

Figure 11.35 A general diagram for the structure of tRNA. The positions of invariant bases as well as bases that seldom vary are shown in color. R = purine; Y = pyrimidine. Dotted lines denote sites in the D loop and variable loop regions where varying numbers of nucleotides are found in different tRNAs. Inset: An aminoacyl group can add to the 3'-OH to create an aminoacyl-tRNA (shown at lower right highlighted in pink).

amino acid is linked to the 3'-OH of the 3'-terminal A nucleotide, thus forming an aminoacyl ester (Figure 11.35). The 3'-end of tRNA is invariantly CCA-3'-OH. The *D loop* is so named because this tRNA loop often contains dihydrouridine, or D, residues. In addition to dihydrouridine, tRNAs characteristically contain a number of unusual bases, including inosine, thiouridine, pseudouridine, and hypermethylated purines (see Figure 10.23). The *anticodon stem-loop* consists of a double helical segment and seven unpaired bases, three of which are the **anticodon**—a three-nucleotide unit that recognizes and base pairs with a particular mRNA **codon**, a complementary three-base unit in mRNA providing the genetic information that specifies an amino acid. In the 5'→3' direction beyond the anticodon stem-loop lies a loop that varies from tRNA to tRNA in the number of residues that it has, the so-called **extra** or **variable loop**. The last loop in the tRNA, reading 5'→3', is within the **TψC stem-loop**. It contains seven unpaired bases, including the sequence TψC, where ψ is the symbol for **pseudouridine**. Most of the invariant residues common to tRNAs lie within the non-hydrogen-bonded regions of the cloverleaf structure.

tRNA Tertiary Structure Tertiary structure in tRNA arises from base-pairing interactions between bases in the D loop with bases in the variable and TψC loops, as shown for yeast phenylalanine tRNA in Figure 11.36. Note that these base-pairing interactions involve the invariant nucleotides of tRNAs. These interactions fold the D and TψC arms together and bend the cloverleaf into the stable L-shaped tertiary form (Figure 11.37). Many of these base-pairing interactions involve base pairs that are not canonical A:T or G:C pairings, as illustrated around the central ribbon diagram of the tRNA in Figure 11.37. Note that three of the interactions involve three bases. The amino acid acceptor stem (highlighted in green) is at one end of the inverted, backward L shape, separated by 7 nm or so from the anticodon at the opposite end of the L. The D and TψC loops form the corner of the L. Hydrophobic stacking interactions between the flat faces of the bases contributes significantly to L-form stabilization.

11.7b Messenger RNA Adopts Higher-Order Structure Through Intrastrand Base Pairing

Messenger RNA (mRNA) directs the synthesis of proteins. The defining feature of an mRNA is its primary structure—its specific nucleotide sequence. This sequence is translated by ribosomes into a unique amino acid sequence. Nevertheless, mRNA

Figure 11.36 Tertiary interactions in yeast phenylalanine tRNA. The molecule is presented in the conventional cloverleaf secondary structure generated by intrastrand hydrogen bonding. Solid red lines connect bases that are hydrogen bonded when this cloverleaf pattern is folded into the characteristic tRNA tertiary structure.

has regions of secondary structure that arise when base pairing takes place between intrastrand complementary regions. That is, like other RNAs, mRNA folds back on itself, forming stem-loop secondary structures, as well as more complex tertiary structures. The stability of these structures depends on the degree of base pairing. Since each mRNA has a unique nucleotide sequence, the secondary and tertiary structures of each are unique. The 5'- and 3'-untranslated (and intron) regions, whose sequences are not constrained by the necessity of encoding a protein, often show higher orders of structure. However, the coding region may also have structured elements. The stability of these various structures in a particular mRNA can affect its translation efficiency, since the mRNA must be unfolded to be read by the ribosome. Thus, higher orders of structure in mRNAs can influence gene expression.

11.7c Ribosomal RNA Also Adopts Higher-Order Structure Through Intrastrand Base Pairing

Ribosomal rRNA provides the structural framework of the ribosome, 16S rRNA for the small ribosomal subunit and 23S and 5S rRNAs for the large ribosomal subunit. Further, the 23S rRNA is a ribozyme and it catalyzes synthesis of the peptide bonds that link amino acids together to form proteins.

Figure 11.37 The three-dimensional structure of yeast phenylalanine tRNA. (a) The tertiary folding is illustrated in the center of the diagram with the ribose-phosphate backbone presented as a continuous ribbon; H bonds are indicated by crossbars. Unpaired bases are shown as short, unconnected rods. The anticodon loop is at the bottom and the -CCA 3'-OH acceptor end is at the top right. (b) A space-filling model of the molecule (PDB id = 6TNA).

rRNA Secondary Structure A large degree of *intrastrand sequence complementarity* is found in all ribosomal RNA strands, and all assume a highly folded pattern that allows base pairing between these complementary segments, giving rise to multiple stem-loop structures. Furthermore, the loop regions of stem-loops contain the characteristic structural motifs, such as U-turns, tetraloops, and bulges. Figure 11.38 shows the secondary structure of several 16S rRNAs. These structures were not determined by direct analysis; instead they were generated through computer alignment of each nucleotide sequence into optimal H-bonding segments. The reliability of these alignments is then tested through a comparative analysis of whether very similar secondary structures are observed. If so, then such structures are apparently conserved. The approach is based on the thesis that because ribosomal RNA species (regardless of source) serve common roles in protein synthesis, it may be anticipated that they share structural features. These secondary structures resemble one another, even though the nucleotide sequences of these 16S rRNAs exhibit little sequence similarity. Apparently, evolution is acting at the level of rRNA secondary structure, not rRNA nucleotide sequence. Similar conserved folding patterns are seen for the 5S-like rRNAs and 23S-like rRNAs that reside in the large ribosomal subunits of various

species. An insightful conclusion may be drawn regarding the persistence of such strong secondary structure conservation despite the millennia that have passed since these organisms diverged: *All ribosomes are similar, and all function in a similar manner.* As usual with RNAs, the single-stranded regions of rRNA create the possibility of base-pairing opportunities with distant, complementary, single-stranded regions. Such interactions are the driving force for tertiary structure formation in RNAs.

rRNA Tertiary Structure The detailed structure of ribosomes has been revealed through X-ray crystallography and cryoelectron microscopy of ribosomes. These detailed images not only disclose the tertiary structure of the rRNAs but also the quaternary interactions that must occur when ribosomal proteins combine with rRNAs and when the ensuing ribonucleoprotein complexes, the small and large subunits, come together to form the complete ribosome. Only the rRNAs of the 50S ribosomal subunit are shown in Figure 11.39; *no* ribosomal proteins are shown. Note that the overall anatomy of the 50S ribosomal subunit (shown diagrammatically in Figure 10.22) is essentially the same as that of the rRNA molecules within this subunit, even though these rRNAs account for only 65% of the mass of this particle. An assortment of tertiary structural features are found in the rRNAs, including coaxial stacks, pseudoknots, and ribose zippers. Peptide bond formation, the key reaction in protein synthesis, is catalyzed by the large rRNA in the large ribosomal subunit (the 23S rRNA in the case of prokaryotic ribosomes and the 28S rRNA of eukaryotic ribosomes). That is, the ribosome is an RNA-based enzyme.

11.7d Aptamers Are Oligonucleotides Specifically Selected for Their Ligand-Binding Ability

Aptamers are oligonucleotides, usually RNA, which fold into very specific three-dimensional structures that selectively bind ligands with high affinity. Ligand binding by aptamers is based on the fundamental principle of structural complementarity. The rich array of interactive possibilities presented by the four bases and the sugar–phosphate backbone, coupled with the inherent flexibility of polynucleotide chains, make nucleic acids very good ligand-binding candidates. The bases project polar amino and carbonyl functionalities, and their π -electron density gives them nonpolar properties. The sugar–phosphate backbone presents polar —OH groups and regularly spaced, negatively charged phosphate groups. These phosphate groups can

Figure 11.38 Comparison of secondary structures of 16S-like rRNAs from (a) a bacterium (*E. coli*), (b) an archaeon (*H. volcanii*), and (c) a eukaryote (*S. cerevisiae*, a yeast).

Figure 11.39 The secondary and tertiary structures of rRNAs in the 50S ribosomal subunit from the archaeon *Haloarcula marismortui* (PDB id = 1FFk). (a) Secondary structure of the 23S rRNA, with various domains color-coded. (b) Secondary structure of 5S rRNA. (c) Tertiary structure of the 5S and 23S rRNAs within the 50S ribosomal subunit. The 5S rRNA (red) lies atop the 23S rRNA. (Adapted from Figure 4 in Ban, N., et al., 2000. The complete atomic structure of the large ribosomal subunit at 2.4 Å resolution. *Science* **289**:905–920.) Although the 5S rRNA of eukaryotes is the same size as this archaeon 5S rRNA, the large rRNA of the large ribosomal subunit in eukaryotes has 2,000 more nucleotides than this 23S rRNA (over 5000 vs. fewer than 3000).

Figure 11.40 Structure of the thiamine pyrophosphate (TPP) riboswitch, a conserved region within the mRNA that encodes enzymes for synthesis of this coenzyme (PDB id = 2CKY). TPP, a pyrimidine-containing compound, is shown in orange. (From Figure 1b in Thore, S., Leibundgut, M., and Ban, N., 2006. Structure of the eukaryotic thiamine pyrophosphate riboswitch with its regulatory ligand. *Science* **312**:1208–1211.)

coordinate cations and thus provide foci of positive charge. Synthetic aptamers designed to target a selected protein can be potent inhibitors of protein function; they are of interest in drug development.

Riboswitches, a naturally occurring class of aptamers, are conserved regions of mRNAs that reversibly bind specific metabolites and coenzymes and usually act as regulators of gene expression. Riboswitches are usually buried within the 5'- or 3'-untranslated regions of the mRNAs whose expression they regulate. Binding of the metabolite to the riboswitch typically blocks expression of the mRNA. Figure 11.40 shows the structure of the thiamine pyrophosphate riboswitch.

Foundational Biochemistry Things You Should Know after Reading Chapter 11.

- DNA sequencing: Sanger's chain termination protocol based on dideoxynucleotides uses DNA replication to generate a defined set of polynucleotide fragments.
- The nucleotide sequence of DNA can be determined from the electrophoretic migration of a defined set of polynucleotide fragments.
- Many ultra-high-throughput methodologies for DNA sequencing also rely on DNA polymerase-driven primer extension to copy unknown DNA sequences.
- Ultra-high-throughput sequencing technologies use light emission, fluorescence detection, or pH change to follow DNA polymerase-catalyzed nucleotide addition and note which base was added. These reactions can be carried out on millions of different DNA strands at the same time, all of which are immobilized on beads or glass surfaces.
- Single-molecule real-time DNA sequencing methods, based either on DNA polymerase action as revealed by fluorescent light pulses or by changes in electrical potential as DNA strands are drawn through nanopores in a synthetic membrane, yield much longer read lengths.
- Long reads have been used to determine the complete sequence of entire human chromosomes.
- DNA structure: The sugar-phosphate backbone of nucleic acids has six degrees of freedom. Rotation about the C_{1'}-N glycosidic bond creates a seventh degree of freedom.
- DNA usually occurs in the form of double-stranded molecules.
- The Watson-Crick base pairs (A-T; G-C) have virtually identical dimensions.
- The DNA double helix is stabilized by H bonds, electrostatic interactions, and the van der Waals and hydrophobic interactions arising from base-pair stacking.
- The DNA double helix has a major groove and a minor groove.
- DNA double helices can occur as A-, B-, or Z-DNA conformations; the B-DNA conformation is the canonical form for double-helical DNA.
- Z-DNA is a left-handed double helix.
- RNA double helices and hybrid DNA:RNA helices adopt the A-conformation due to steric hindrance caused by the RNA 3'-OH groups.
- Alternative H-bonding interactions give rise to novel DNA structures, such as cruciforms, triplexes, and quadruplexes.
- Hoogsteen base pairs, an alternative mode of base-pair formation, arise in triplex DNA structures known as H-DNA.
- Thermal denaturation of DNA can be followed by observing increases in UV absorbance.
- Single-stranded DNA can renature (re-anneal) to form DNA duplexes.
- The rate of DNA renaturation is a measure of DNA sequence complexity.
- Supercoils are one kind of structural complexity in DNA. Supercoils alter the topological state of DNA.
- Supercoils can be positive (overwound DNA) or negative (underwound DNA), relative to B-DNA.
- The linking number, L , of double-helical DNA is given by $L = T + W$, where T = twist (the number of helical turns in a DNA molecule) and W = writhe (the number of supercoils).
- Topoisomerases are enzymes that change the topological state of DNA.
- Eukaryotic DNA: Nucleosomes are the fundamental structural unit of chromatin.
- Chemical synthesis of DNA has led to the creation of synthetic chromosomes.
- The ability to chemically synthesize DNA is termed "DNA-write."
- DNA as code: The information encoded in DNA is analogous to computer code.
- DNA is an excellent data storage system.
- Nucleic acids can be created synthetically, using an orthogonal procedure and phosphoramidite chemistry.
- RNA molecules are rich in secondary structures formed through intrastrand H-bonding.
- RNAs contain a variety of structural motifs, such as stem-loops, U-turns, tetraloops, bulges, junctions, and coaxial stacks.
- Transfer RNA adopts higher-order structure through base-pairing interactions between the single-stranded regions of stem-loop structures.
- Ribosomal RNA also adopts higher-order structure through base-pairing interactions between the single-stranded regions of stem-loop structures.
- Ribosomal RNAs adopt an evolutionarily conserved secondary structure.
- Aptamers are oligonucleotides with highly selective ligand-binding ability.
- Riboswitches are naturally occurring aptamers involved in regulating the expression of genetic information.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Predicting a Sanger Sequencing Pattern** The oligonucleotide d-AGATGCCTGACT was subjected to sequencing by Sanger's dideoxy method, using fluorescent-tagged dideoxynucleotides and capillary electrophoresis, essentially as shown in Figure 11.3. Draw a diagram of the gel-banding pattern within the capillary.
- Sanger's Method of DNA Sequencing** Consider the DNA fragment shown. Using TAGCT as the primer, show all the fragments that would be generated by Sanger sequencing. Refer to Figure 11.3 and use the following color coding: green for ddG, blue for ddC, orange for ddA and red for ddT. Alternatively the following shape coding could be used: ■ for ddG, ▲ for ddC, ● for ddA, and ◆ for ddT.
5'-CCTAGGCATGAACTCTGTAATCGACTATGC-3'
- Deducing DNA Sequence from Sanger Sequencing Results** The output of an automated DNA sequence determination by the Sanger dideoxy chain termination method, performed as illustrated in Figure 11.4, was recorded as a series of light flashes in the following order (where B = blue, G = green, R = red, and Y = yellow): YYGGRRGYR-BRRRGGBRRRB. What is the sequence of the original oligonucleotide?
- Helical Parameters for a Double-Stranded DNA** X-ray diffraction studies indicate the existence of a double-stranded DNA helical conformation in which ΔZ (the rise per base pair) = 0.32 nm and P (the pitch) = 3.36 nm. What are the other parameters of this novel helix: (a) the number of base pairs per turn, (b) $\Delta\phi$ (the mean rotation per base pair), and (c) c (the true repeat)?
- B- and Z-DNA Helical Parameters I** A 41.5 nm-long duplex DNA molecule in the B-conformation adopts the A-conformation upon dehydration. How long is it now? What is its approximate number of base pairs?
- B- and Z-DNA Helical Parameters II** If 80% of the base pairs in a duplex DNA molecule (12.5 kbp) are in the B-conformation and 20% are in the Z-conformation, what is the length of the molecule?
- DNA Supercoiling Parameters** A "relaxed," circular, double-stranded DNA molecule (1600 bp) is in a solution where conditions favor 10 bp per turn. What is the value of L_0 for this DNA molecule? Suppose DNA gyrase introduces 12 negative supercoils into this molecule. What are the values of L , W , and T now? What is the superhelical density, σ ?
- B- and Z-DNA Supercoiling Parameters** Suppose one double helical turn of a superhelical DNA molecule changes conformation from B- to Z-form. What are the changes in L , W , and T ? Why do you suppose the transition of DNA from B- to Z-form is favored by negative supercoiling?
- Calculate the Number of Nucleosomes in a Human Diploid Cell** Assume that there is one nucleosome for every 200 bp of eukaryotic DNA. How many nucleosomes are there in a diploid human cell? Nucleosomes can be approximated as disks 11 nm in diameter and 6 nm long. If all the DNA molecules in a diploid human cell are in the B-conformation, what is the sum of their lengths? If this DNA is now arrayed on nucleosomes in the beads-on-a-string motif, what would be the approximate total height of the nucleosome column if these disks were stacked atop one another?
- The Linear Arrangement of Complementary Sequences along the tRNA Strand** The characteristic secondary structures of tRNA and rRNA molecules are achieved through intrastrand hydrogen bonding. Even for the small tRNAs, remote regions of the nucleotide sequence interact via H bonding when the molecule adopts the cloverleaf pattern. Using Figure 11.35 as a guide, draw the primary structure of a tRNA and label the positions of its various self-complementary regions.
- Using Chargaff's Results to Order DNAs According to Their T_m s** Using the data in Table 10.1, arrange the DNAs from the following sources in order of increasing T_m : human, salmon, wheat, yeast, *E. coli*.
- Calculating T_m s and Separating DNA Molecules That Differ in G:C Content** At 0.2 M Na⁺, the melting temperature of double-stranded DNA is given by the formula, $T_m = 69.3 + 0.41 (\% G + C)$. The DNAs from mice and rats have (G + C) contents of 44% and 40%, respectively. Calculate the T_m s for these DNAs in 0.2 M NaCl. If samples of these DNAs were inadvertently mixed, how might they be separated from one another?
- Calculating the Density of DNAs That Differ in G:C Content** The buoyant density of DNA is proportional to its (G + C) content. (G:C base pairs have more atoms per volume than A:T base pairs.) Calculate the density (ρ) of *Serratia marcescens* DNA from the data presented in Table 10.1 and the equation $\rho = 1.660 + 0.098(\text{GC})$, where (GC) is the mole fraction of (G + C) in DNA.
- Draw a ψ :G Base Pair** (Integrates with Chapter 10.) Pseudouridine (ψ) is an invariant base in the T ψ C loop of tRNA; ψ is also found in strategic places in rRNA. (Figure 10.22 shows the structure of pseudouridine.) Draw the structure of the base pair that ψ might form with G.
- The Dimensions of Closed Circular DNA Molecules** The plasmid pBR322 is a closed circular dsDNA containing 4363 base pairs. What is the length in nm of this DNA (that is, what is its circumference if it were laid out as a perfect circle)? The *E. coli* K12 chromosome is a closed circular dsDNA of about 4,639,000 base pairs. What would be the circumference of a perfect circle formed from this chromosome? What is the diameter of a dsDNA molecule? Calculate the ratio of the length of the circular plasmid pBR322 to the diameter of the DNA of which it's made. Do the same for the *E. coli* chromosome.
- Identifying DNA Structural and Functional Elements from Nucleotide Sequence Information** Listed below are four DNA sequences. Which one contains a type-II restriction endonuclease ("six-cutter") hexanucleotide site? Which one is likely to form a cruciform structure? Which one is likely to be found in Z-DNA? Which one represents the 5'-end of a tRNA gene? Which one is most likely to be found in a triplex DNA structure?
 - CGCGCGCCGCGCACGCGCTCGCGCGCCGC
 - GAACGTCGTATTCCCGTACGACGTTT
 - CAGGTCTCTCTCTCTCTCTCTCT
 - TGGTGCGAATTCTGTGGAT
 - ATCGGAATTCATCG
- Interactions between amino acids and DNA. (Integrated with Chapter 4)** Refer to Figure 4.3. Which amino acids may interact with DNA through
 - hydrogen bonding,
 - ionic interactions, or
 - intercalating interactions? Explain your answer
- Draw the Cloverleaf Structure of a tRNA from RNA Sequence Information** The nucleotide sequence of *E. coli* tRNA^{Gln} is as follows:
UGGGGUAUCG₁₀CCAAGC–GGU₂₀AAGGCACCGG₃₀AU–UCUGA Ψ Ψ C₄₀CGGCAUUCG₅₀AGGT Ψ CGAAU₆₀CCUCGUA–CCC₇₀CAGCCA₇₆
From this primary structure information, draw the secondary structure (cloverleaf) of this RNA and identify its anticodon.
- Cruciform DNA** Consider the dsDNA shown and draw a possible cruciform structure for this DNA segment.
5'-CGATAGTCCATGCCTAGCATGGACTTAATGC-3'
3'-GCTATCAGGTACGGATCGTACCTGAATTACG-5'

20. Use the Tools of the Protein Data Bank to Explore Ribosome Structure

The Protein Data Bank (PDB) is also a repository for nucleic acid structures. Go to the PDB at www.rcsb.org and enter pdb id = 1Y12. 1Y12 is the PDB ID for the structure of the *H. marismortui* 50S ribosomal subunit with erythromycin bound. Erythromycin is an antibiotic that acts by inhibiting bacterial protein synthesis. In the list of the display options under the image of the 50S subunit, click on one of the viewing options to view the structure. Using the tools of the viewer, zoom in and locate erythromycin within this structure. If the 50S ribosomal subunit can be compared to a mitten, where in the mitten is erythromycin?

21. Use the Human Genome Database to Explore the Relationship Between Genes, Proteins, and Diseases

Online resources provide ready access to detailed information about the human genome. Go the National Center for Biotechnology Information (NCBI) genome database at <http://www.ncbi.nlm.nih.gov/Genomes/index.html>. Under the “Custom Resources” page that appears, click on “Human Genome.” Click on “Chromosome 6” in the array of displayed chromosomes. In the Genome Data Viewer page that comes up, locate the “Search assembly” box, type in “TNF,” and click on the arrow to start the search. Note the TNF chromosome 6 location information for TNF displayed in the box below the “Search assembly” box. This information is given in base pairs. Scroll over the NM_000594.4 transcript displayed to the right to reveal further information about TNF.

- What does TNF stand for?
- What is the chromosomal location of TNF in base pairs?
- How many exons does the TNF gene have?
- How many amino acid residues does the TNF protein have?

22. G:C Content in Bacteria (Integrates with Chapter 10.) Erwin Chargaff did not have any DNA samples from thermoacidophilic bacteria such as those that thrive in the geothermal springs of Yellowstone National Park. (Such bacteria had not been isolated by 1951 when Chargaff reported his results.) If he had obtained such a sample, what do you think its relative G:C content might have been? Why?**23. Structural Features of B-form DNA** Think about the structure of DNA in its most common B-form double helical conformation and then list its most important structural features (deciding what is “important” from the *biological* role of DNA as the material of heredity). Arrange your answer with the most significant features first.**24. The Dimensions of DNA** An average base pair in DNA contributes 10^{-21} g to the weight and 0.32 nm to the length of a DNA molecule.

- What is the total weight and total length of the DNA contained in a human cell?
 - The circumference of the earth at the equator is about 40,000 km. How many base pairs would a double-stranded DNA molecule that circled the earth have?
 - How much would it weigh?
- The distance from the earth to the sun = 150 million km.
- How many base pairs would a double-stranded DNA that stretched from the earth to the sun have?
 - How much would such a DNA molecule weigh?

25. How Structural Differences Between DNA and RNA Affect Its Properties

Cellular DNA molecules are double stranded. RNAs are single-stranded molecules with double-stranded regions. For each of the following properties, describe how DNA and RNA may differ and why.

- Hyperchromic shift
- Colligative properties of DNA vs. RNA
- Inverted repeats
- T_m (melting points)
- Buoyant density
- Chemical and physical stability

26. Modified Nucleotides in DNA or RNA The bases found in DNA or RNA are often chemically modified. Methylation (addition of $-\text{CH}_3$) of C in DNA (see Box Human Biochemistry DNA methylation, CpG Islands, and Epigenetics) or of other bases in RNA are very common modifications. When noting methylation, both the base and the exact position that is methylated are described. As an example, the presence of “m⁵C” in a sequence would indicate that cytosine is methylated in position 5. Revisit Figures 10.2, 10.3, and 10.4 and draw the structures of m³C, m⁵C, m⁷G, m¹A, and m⁶A.**27. DNA Bending** As evident from Problem 24, double-stranded DNA molecules are extremely long and extremely thin. Over short distances, such molecules behave in solution like a rigid rod, but over long distances, they act more like flexible noodles (see Figure 11.30). DNA flexibility is essential to its compaction in the nucleus. **Persistence length** is the physical property that defines the bending stiffness of polymers. Sections of the polymer shorter than the persistence length behave like rigid rods. The path of sections much longer than the persistence length is random and can only be described statistically. Double-helical DNA has a persistence length of about 40 nm. How many helical turns of B-form DNA occur in a distance of 40 nm? How many base pairs? Human chromosome 8 has a DNA molecule that is 146,259,671 bp-long. What is the ratio of the overall length of this DNA to its persistence length? What effect might the organization of DNA into chromatin have on its persistence length?**Think-Pair-Share Question**

Gene Sequencing with Procedural Mistakes A segment of DNA was sequenced using the Sanger method (see Section 11.1b and Figure 11.3) but mistakes were made during the process:

The segment was sequenced in the absence of:

- ddATP and the following sequence was obtained: TCCGTTGGCTTGCTCC
- ddCTP and the following sequence was obtained: TAGTTAGGTTGAT
- ddTTP and the following sequence was obtained: ACCGAGCGCACC
- ddGTP and the following sequence was obtained: TACCTTACTTCATCC

What was the sequence of the original segment of DNA?

Recombinant DNA, Cloning, Gene Editing, and Synthetic Biology—An Introduction

12

...how many vain chimeras have you created? ...
Go and take your place with the seekers after gold.

Leonardo da Vinci
The Notebooks (1508–1518), Volume II,
Chapter 25

Scala/Art Resource, NY

◀ The Chimera of Arezzo, of Etruscan origin and probably from the fifth century B.C., was found near Arezzo, Italy, in 1553. Chimeric animals existed only in the imagination of the ancients. But the ability to create chimeric DNA molecules is a very real technology that has opened up many new avenues of scientific investigation.

Essential Questions

Using techniques for the manipulation of nucleic acids in the laboratory, scientists can join together DNA segments from different sources. Such manmade products are called recombinant DNA molecules, and the use of such molecules to alter the genetics of organisms is termed genetic engineering. **What are the methods that scientists use to create recombinant DNA molecules; can scientists create genes from recombinant DNA molecules; and can scientists modify the heredity of an organism using recombinant DNA?**

Technologies for the laboratory manipulation of nucleic acids emerged in the early 1970s. In turn, these technologies led to the construction of DNA molecules composed of nucleotide sequences taken from different sources. The products of these innovations, **recombinant DNA molecules**,¹ opened exciting new opportunities in molecular biology and genetics, and a new field was born—**recombinant DNA technology**. **Genetic engineering** is the application of this technology to the manipulation of genes. These advances were made possible by methods for **amplification** of any DNA segment of interest, regardless of source, within bacterial host cells and later on, eukaryotic cells, including those of mammals. In the language of recombinant DNA technology, the **cloning** of virtually any DNA sequence became feasible. Cloning has led to methodologies to identify specific DNA and RNA sequences among an overwhelming amount of extraneous nucleic acid, to express cloned genes and produce desired proteins in cell cultures, to inactivate gene expression, to edit DNA nucleotide sequences, and to alter the metabolism by introducing new enzymes, to list just a few of the achievements. Parallel advances in nanotechnology and microfluidics render these methodologies even more powerful. What follows is an introduction and overview of what is possible today. Tomorrow will bring even more dramatic technology for DNA, RNA, and protein analysis.

¹The advent of molecular biology, like that of most scientific disciplines, generated a jargon all its own. Learning new fields often requires gaining familiarity with a new vocabulary. We will soon see that many words—*vector*, *amplification*, and *insert* are but a few examples—have new meanings that describe the marvels of molecular biology.

Key Questions

- 12.1 What Is DNA Cloning?
- 12.2 What Is a DNA Library?
- 12.3 Can the Genes in Libraries Be Transcribed and Translated?
- 12.4 How Is RNA Interference Used to Reveal the Function of Genes?
- 12.5 Gene Therapy: Is It Possible for Scientists to Alter or Rewrite the Genome of an Organism?
- 12.6 How Does High-Throughput Technology Allow Global Study of Millions of Genes or Molecules at Once?
- 12.7 What Is the Field of Synthetic Biology?

12.1 | What Is DNA Cloning?

In classical biology, a *clone* is a population of identical organisms derived from a single parental organism. For example, the members of a colony of bacterial cells that arise from a single cell on a petri plate are a clone. Molecular biology has borrowed the term to mean a collection of molecules or cells all identical to an original molecule or cell. So, if a single bacterial cell harboring a recombinant DNA molecule in the form of a plasmid grows and multiplies on a petri plate to form a colony, the plasmids within the millions of cells in the bacterial colony represent a clone of the original DNA molecule, and these molecules can be isolated and studied. Furthermore, if the cloned DNA molecule contains a gene (or part of a gene)—that is, it encodes a functional product—a new avenue to isolating and studying this product has opened. Desired proteins can be produced in abundance, which greatly expands the possibilities for their biochemical analysis and manipulation. Using recombinant DNA molecules that carry genes encoding proteins of interest, new functionalities could be introduced into host cells. Recombinant DNA methodology offers exciting new vistas in biochemistry.

12.1a Plasmids Are Very Useful in Cloning Genes

Plasmids are naturally occurring, circular, extrachromosomal DNA molecules (see Chapter 11). Natural strains of the common colon bacterium *Escherichia coli* isolated from various sources contain diverse plasmids. Often these plasmids carry genes specifying novel metabolic activities that are advantageous to the host bacterium. These activities range from catabolism of unusual organic substances to metabolic functions that endow the host cells with resistance to antibiotics, heavy metals, or bacteriophages. Plasmids that are able to perpetuate themselves in *E. coli*, the bacterium favored by bacterial geneticists and molecular biologists, are the workhorses of recombinant DNA technology. Because restriction endonuclease digestion of plasmids can generate fragments with overlapping or sticky ends, artificial plasmids can be constructed by ligating different fragments together. Such artificial plasmids were among the earliest recombinant DNA molecules. These recombinant molecules can be autonomously replicated, and hence propagated, in suitable bacterial host cells, provided they still possess a site signaling where DNA replication can begin (an **origin of replication** or *ori* sequence).

Plasmids as Cloning Vectors This technique relies on the idea that foreign DNA sequences could be inserted into artificial plasmids and that these foreign sequences would be carried into *E. coli* and propagated as part of the plasmid. That is, these plasmids could serve as **cloning vectors** to carry genes. (The word *vector* is used here in the sense of “a vehicle or carrier.”) Plasmids useful as cloning vectors possess three

Chemistry in History

Tu Youyou

Tu Youyou (1930–present) is a Nobel Prize winning pharmaceutical chemist who discovered both artemisinin, the active component of sweet wormwood, and its active metabolite, dihydroartemisinin, which are used in the treatment of malaria. She was born in 1930 and after having her first year of high school derailed by a tuberculosis infection, she resolved that her goal was to pursue medical science. She graduated from Beijing Medical University School of Pharmacy in 1955.

During the Vietnam War, she was appointed head of a secret government research group whose goal was to create a treatment for chloroquine-resistant malaria. Youyou's study of classical Chinese herbal medicine led her to sweet wormwood (*Artemisia annua*), an ancient treatment for intermittent fever, a well-known symptom of malaria. Tu Youyou was the first Chinese woman to ever receive a Nobel Prize and her work is credited for saving millions of lives across the world.

Figure 12.2 An *Eco*RI restriction fragment of foreign DNA can be inserted into a plasmid having an *Eco*RI cloning site by (1) cutting the plasmid at this site with *Eco*RI, (2) annealing the linearized plasmid with the *Eco*RI foreign DNA fragment, and (3) sealing the nicks with DNA ligase.

overhangs. Then these ends can base-pair with one another, annealing the two molecules together. One way to generate such ends is to cleave the DNA with restriction enzymes that make staggered cuts; many such restriction endonucleases are available (see Table 10.2). For example, if the sequence to be inserted was generated by *Eco*RI digestion and the plasmid is cut with *Eco*RI, the single-stranded sticky ends of the two DNAs can anneal (Figure 12.2). The interruptions in the sugar–phosphate backbone of DNA can then be sealed with DNA ligase to yield a covalently closed, circular chimeric plasmid. DNA ligase is an enzyme that covalently links adjacent 3′-OH and 5′-PO₄ groups. An inconvenience of this strategy is that *any* pair of *Eco*RI sticky ends can anneal with each other. So, plasmid molecules can reanneal with themselves, as can the foreign DNA restriction fragments. These DNAs can be eliminated by selection schemes designed to identify only those bacteria containing chimeric plasmids.

Blunt-end ligation is an alternative method for joining different DNAs. The most widely used DNA ligase, **bacteriophage T4 DNA ligase**, is an ATP-dependent enzyme that can even ligate two DNA fragments whose ends lack overhangs (blunt-ended DNAs). Many restriction endonucleases cut double-stranded DNA so that blunt ends are formed.

An astounding number of variations on these basic themes has emerged. For example, short synthetic DNA duplexes whose nucleotide sequence consists of little more than a restriction site can be blunt-end ligated onto any DNA. These short DNAs are known as **linkers**. Cleavage of the ligated DNA with the restriction enzyme then leaves tailor-made sticky ends useful in cloning reactions (Figure 12.3). Similarly, many vectors contain a **polylinker** cloning site, a short region of DNA sequence bearing numerous restriction sites.

Promoters and Directional Cloning Note that the strategies discussed thus far create hybrids in which the orientation of the DNA insert within the chimera is random. Sometimes it is desirable to insert the DNA in a particular orientation. For example, an experimenter might wish to insert a particular DNA segment (a gene) in a vector so that its gene product is synthesized. To do this, the DNA must be placed downstream from a **promoter**. A promoter is a nucleotide sequence lying upstream of a gene. The promoter controls expression of the

Figure 12.3 The use of linkers to create tailor-made ends on cloning fragments. **(a)** The ligation reaction can add multiple linkers on each end of the blunt-ended DNA. *EcoRI* digestion removes all but the terminal one, leaving the desired 5'-overhangs.

(b) Cloning vectors often have polylinkers consisting of a multiple array of restriction sites at their cloning sites, so restriction fragments generated by a variety of endonucleases can be incorporated into the vector. Note that the polylinker is engineered not only to have multiple restriction sites, but also to have an uninterrupted sequence of codons, so this region of the vector has the potential for translation into protein (see Figure 12.15). (Adapted from Figure 1.14.2 in Greenwich, D., and Brent, R., *UNIT 1.14*

Introduction to Vectors Derived from Filamentous Phages, in *Current Protocols in Molecular Biology*, Ausubel, F. M., et al., eds. New York: John Wiley and Sons, 2003.)

gene. RNA polymerase molecules bind specifically at promoters and initiate transcription of adjacent genes, copying template DNA into RNA products. One way to insert DNA so that it will be properly oriented with respect to the promoter is to create DNA molecules whose ends have different overhangs. Ligation of such molecules into the plasmid vector can only take place in one orientation to give **directional cloning** (Figure 12.4).

Figure 12.4 Directional cloning. DNA molecules whose ends have different overhangs can be used to form chimeric constructs in which the foreign DNA can enter the plasmid in only one orientation. The foreign DNA and the plasmid are digested with the same two enzymes. pUC stands for universal cloning plasmid.

Biologically Functional Chimeric Plasmids The first biologically functional chimeric DNA molecules constructed *in vitro* were assembled from parts of different plasmids in 1973 by Stanley Cohen, Annie Chang, Herbert Boyer, and Robert Helling. These plasmids were used to **transform** recipient *E. coli* cells (*transformation* means the uptake and replication of exogenous DNA by a recipient cell). To facilitate transformation, the bacterial cells were rendered somewhat permeable to DNA by Ca^{2+} treatment and a brief 42°C heat shock. Although less than 0.1% of the Ca^{2+} -treated bacteria became competent for transformation, transformed bacteria could be selected by their resistance to certain antibiotics (Figure 12.5). Consequently, the chimeric plasmids must have been biologically functional in at least two aspects: They replicated stably within their hosts, and they expressed the drug resistance markers they carried.

Figure 12.5 A typical bacterial transformation experiment. Here the plasmid pBR322 is the cloning vector. (1) Cleavage of pBR322 with *Bam*HI, followed by (2) annealing and ligation of inserts generated by *Bam*HI cleavage of some foreign DNA, (3) creates a chimeric plasmid. (4) The chimeric plasmid is then used to transform Ca^{2+} -treated heat-shocked *E. coli* cells, and the bacterial sample is plated on a petri plate. (5) Following incubation of the petri plate overnight at 37°C . (6) Colonies of *amp^r* bacteria are evident. (7) Replica plating of these bacteria on plates of tetracycline-containing media (8) reveals which colonies are *tet^r* and which are tetracycline sensitive (*tet^s*). Only the *tet^r* colonies possess plasmids with foreign DNA inserts.

In general, plasmids used as cloning vectors are engineered to be small (2.5 kbp to about 10 kbp in size) so that the size of the insert DNA can be maximized. These plasmids have only a single origin of replication, so the time necessary for complete replication depends on the size of the plasmid. Under selective pressure in a growing culture of bacteria, overly large plasmids are prone to delete any nonessential genes, such as any foreign inserts. Such deletion would thwart the purpose of most cloning experiments. The useful upper limit on cloned inserts in typical plasmids is about 10 kbp. Many eukaryotic genes exceed this size. F', an atypical plasmid, can carry foreign DNA inserts of 350 kbp or more. Recombinant F' constructs, called **BACs**, for **bacterial artificial chromosomes**, have proven to be very useful in cloning eukaryotic DNA in bacterial hosts.

12.1b Shuttle Vectors Are Plasmids That Can Propagate in Two Different Organisms

Shuttle vectors are plasmids capable of propagating and transferring (shuttling) genes between two different organisms, one of which is typically a prokaryote (*E. coli*) and the other a eukaryote (for example, yeast). Shuttle vectors must have unique origins of replication for each cell type and different markers for the selection of transformed host cells harboring the vector (Figure 12.6). Shuttle vectors have the advantage that eukaryotic genes can be cloned in bacterial hosts, yet the expression of these genes can be analyzed in appropriate eukaryotic cells.

12.1c Artificial Chromosomes Can Be Created from Recombinant DNA

DNA molecules two megabase pairs in length have been successfully propagated in yeast by creating **yeast artificial chromosomes**, or **YACs**. Furthermore, such YACs have been transferred into transgenic mice for the analysis of large genes or multigenic DNA sequences *in vivo*, that is, within the living animal. For these large DNAs to be replicated in the yeast cell, YAC constructs must include not only an origin of replication (known in yeast terminology as an *autonomously replicating sequence* or *ARS*) but also a centromere and telomeres. Recall that centromeres provide the site for attachment of the chromosome to the spindle during mitosis and meiosis, and telomeres are nucleotide sequences defining the ends of chromosomes. Telomeres are essential for proper replication of the chromosome.

Figure 12.6 A typical shuttle vector. LEU21 is a gene in the yeast pathway for leucine biosynthesis. The recipient yeast cells are LEU2⁻ (defective in this gene) and thus require leucine for growth. LEU2⁻ yeast cells transformed with this shuttle vector can be selected on medium lacking any leucine supplement.

Human artificial chromosomes, or **HACs**, have also been created. HACs typically carry 5 to 10×10^3 kbp of DNA, including features required for chromosome replication, such as centromeres, telomeres, and replication origins (normal human chromosomes have 50 to 250×10^3 kbp of DNA). HACs are constructed by removing most of the DNA from a selected human chromosome and then introducing one or more genes of interest. HACs offer the advantage of introducing large amounts of recombinant DNA into human cells, ideally for the treatment of disease.

12.2 | What Is a DNA Library?

A DNA library is a set of cloned fragments that collectively represent the genes of a specific organism. Particular genes can be isolated from DNA libraries, much as books can be obtained from conventional libraries. The secret is knowing where and how to look.

12.2a Genomic Libraries Are Prepared from the Total DNA in an Organism

Any particular gene constitutes only a small part of an organism's genome. For example, if the organism is a mammal whose entire genome exceeds 10^6 kbp and the gene is 10 kbp, then the gene represents less than 0.001% of the total nuclear DNA. It is impractical to attempt to recover such rare sequences directly from isolated nuclear DNA because of the overwhelming amount of extraneous DNA sequences. Instead, a **genomic library** is prepared by isolating total DNA from the organism, digesting it

Critical Developments in Biochemistry

Combinatorial Libraries

Specific recognition and binding of other molecules is a defining characteristic of any protein or nucleic acid. Often, target ligands of a particular protein are unknown, or in other instances, a unique ligand for a known protein may be sought in the hope of blocking the activity of the protein or otherwise perturbing its function. Or, the hybridization of nucleic acids with each other according to base-pairing rules, as an act of specific recognition, can be exploited to isolate or identify pairing partners. **Combinatorial libraries** are the products of strategies to facilitate the identification and characterization of macromolecules (proteins, DNA, RNA) that interact with small-molecule ligands or with other macromolecules. Unlike genomic libraries, combinatorial libraries consist of synthetic oligomers. Arrays of synthetic oligonucleotides printed as tiny dots on miniature solid supports are known as **DNA chips**. (See Section 12.2f DNA Microarrays (*Gene Chips*) Are Arrays of Different Oligonucleotides Immobilized on a Chip.)

Specifically, combinatorial libraries contain very large numbers of chemically synthesized molecules (such as peptides or oligonucleotides) with randomized sequences or structures. Such libraries are designed and constructed with the hope that one molecule among a vast number will be recognized as a ligand by the protein (or nucleic acid) of interest. If so, perhaps that molecule will be useful in a pharmaceutical application. For instance, the synthetic oligomer may serve as a drug to treat a disease involving the protein to which it binds.

An example of this strategy is the preparation of a **synthetic combinatorial library** of hexapeptides. The maximum number of sequence combinations for hexapeptides is 20^6 , or 64,000,000. One approach to simplify preparation and screening possibilities for such

a library is to specify the first two amino acids in the hexapeptide, and the next four are randomly chosen. In this approach, 400 libraries (20^2) are synthesized, each of which is unique in terms of the amino acids at positions 1 and 2 but random at the other four positions (as in AAXXXX, ACXXXX, ADXXXX, etc.), so each of the 400 libraries contains 20^4 , or 160,000, different sequence combinations. Screening these libraries with the protein of interest reveals which of the 400 libraries contains a ligand with high affinity. Then, this library is expanded systematically by specifying the first three amino acids (knowing from the chosen 1-of-400 libraries which amino acids are best as the first two); only 20 synthetic libraries (each containing 20^3 , or 8000, hexapeptides) are made here (one for each third-position possibility, with the remaining three positions being randomized). Selection for ligand binding, again with the protein of interest, reveals the best of these 20, and this particular library is then varied systematically at the fourth position, creating 20 more libraries (each containing 20^2 , or 400, hexapeptides). This cycle of synthesis, screening, and selection is repeated until all six positions in the hexapeptide are optimized to create the best ligand for the protein. A variation on this basic strategy using synthetic oligonucleotides rather than peptides identified a unique 15-mer (sequence GGTTGGTGTGGTTGG) with high affinity ($K_D = 2.7$ nM) toward thrombin, a serine protease in the blood coagulation pathway. Thrombin is a major target for the pharmacological prevention of clot formation in coronary thrombosis.

into fragments of suitable size, and cloning the fragments into an appropriate vector. This approach is called **shotgun cloning** because the strategy has no way of targeting a particular gene but instead seeks to clone all the genes of the organism at one time. The intent is that at least one recombinant clone will contain at least part of the gene of interest. Usually, the isolated DNA is only partially digested by the chosen restriction endonuclease so that not every restriction site is cleaved in every DNA molecule. Then, even if the gene of interest contains a susceptible restriction site, some intact genes might still be found in the digest. Genomic libraries have been prepared from thousands of different species.

Many clones must be created to be confident that the genomic library contains the gene of interest. The probability, P , that some number of clones, N , contains a particular fragment representing a fraction, f , of the genome is

$$P = 1 - (1 - f)^N$$

Thus,

$$N = \frac{\ln(1 - P)}{\ln(1 - f)}$$

For example, if the library consists of 10 kbp fragments of the *E. coli* genome (4640 kbp total), more than 2000 individual clones must be screened to have a 99% probability ($P = 0.99$) of finding a particular fragment. Since $f = 10/4640 = 0.0022$ and $P = 0.99$, $N = 2093$. For a 99% probability of finding a particular sequence within the 3×10^6 kbp human genome, N would equal almost 1.4 million if the cloned fragments averaged 10 kbp in size. The need for cloning vectors capable of carrying very large DNA inserts becomes obvious from these numbers.

12.2b Libraries Can Be Screened for the Presence of Specific Genes

Any given DNA fragment is unique solely because of its specific nucleotide sequence. The only practical way to find one particular gene or DNA segment among a vast population of different DNA fragments (such as you might find in genomic DNA preparations) is to exploit its unique sequence to identify it. A simple way to screen genomic libraries is to carry out a **colony hybridization experiment**. In a typical experiment, host bacteria containing a plasmid-based library are plated out on a petri dish and allowed to grow overnight to form colonies (Figure 12.7). A replica of the bacterial colonies is then obtained by overlaying the plate with a flexible, absorbent disc. The disc is removed, treated with alkali to dissociate bound DNA duplexes into single-stranded DNA, dried, and placed in a sealed bag with a labeled **probe**. A probe is usually a single-stranded DNA of defined sequence that is distinctively labeled with some easily detectable marker, such as a fluorescent tag. The nucleotide sequence of the probe is designed to be complementary to the sought-for or *target* DNA fragment. To detect a colony that contains the desired DNA, the prehybridized

Figure 12.7 Screening a genomic library by colony hybridization. Host bacteria transformed with a plasmid-based genomic library are plated on a petri plate and incubated overnight to allow bacterial colonies to form. (1) A replica of the colonies is obtained by overlaying the plate with a flexible disc composed of absorbent material (such as nitrocellulose or nylon). (2) Nitrocellulose strongly binds nucleic acids; single-stranded nucleic acids are bound more tightly. Once the disc has taken up an impression of the bacterial colonies, it is removed and the petri plate is set aside and saved. The disc is treated with 2 M NaOH, neutralized, and dried. NaOH both lyses any bacteria (or phage particles) and dissociates the DNA strands. When the disc is dried, the DNA strands become immobilized on the filter. (3) The dried disc is placed in a sealable plastic bag, and a solution containing heat-denatured (single-stranded), labeled probe is added. (Probes can be labeled in a variety of ways: fluorescent or colored dyes, radioactive isotopes, and more.) The bag is incubated to allow annealing of the probe DNA to any target DNA sequences that might be present on the disc. (4) The filter is then washed, dried, and prepared for visualization of the presence of labeled probe. (5) The position of any spots reveals where the labeled probe has hybridized with target DNA. The location of these spots can be used to recover the genomic clone from the bacteria on the original petri plate.

Known amino acid sequence:

- 3 Incubate disc with probe solution in plastic bag.

- 4 Hybridization of the correct oligonucleotide to the DNA.

- 5 Visualize location of labeled probe on disc.

Figure 12.8 Cloning genes using oligonucleotide probes designed from a known amino acid sequence. A labeled set of DNA (degenerate) oligonucleotides representing all possible mRNA coding sequences is synthesized and is used to probe the genomic library by colony hybridization (see Figure 12.7). (Adapted from Figure 19-18, in Watson, J. D., et al., *Molecular Biology of the Gene* 4/e. Menlo Park, Calif.: Benjamin/Cummings, 1987.)

sheet is incubated in a sealed plastic bag with a solution of specific probe molecules (step 5 in figure). The single-stranded probe DNA **anneals** with the single-stranded target DNA bound to the sheet through specific base pairing to form a DNA duplex. This annealing, or **hybridization** as it is usually called, labels the target DNA, revealing its location. If the probe DNA is duplex DNA, it must be denatured by heating at 70°C. The probe and target DNA complementary sequences must be in a single-stranded form if they are to hybridize with one another. Any DNA sequences complementary to probe DNA will be revealed by the location of the hybridized labeled probe on the absorbent disc. Bacterial colonies containing clones bearing target DNA can be recovered from the master plate.

12.2c Probes for Screening Libraries Can Be Prepared in a Variety of Ways

Clearly, specific probes are essential reagents if the goal is to identify a particular gene or gene fragment against a background of innumerable DNA sequences. Usually, the probes used to screen libraries are nucleotide sequences that are complementary to some part of the target gene. Making useful probes requires some information about the gene's nucleotide sequence. Sometimes, such information is available. Alternatively, if the amino acid sequence of the protein encoded by the gene is known, it is possible to work backward through the genetic code to the DNA sequence (Figure 12.8). Because the genetic code is *degenerate* (that is, several codons may specify the same amino acid; see Chapter 30), probes designed by this approach are usually **degenerate oligonucleotides** about 17 to 50 residues long (such oligonucleotides are 17- to 50-mers). The oligonucleotides are synthesized so that different bases are incorporated at sites where degeneracies occur in the codons. The final preparation thus consists of a mixture of equal-length oligonucleotides whose sequences vary to accommodate the degeneracies. Presumably, one oligonucleotide sequence in the mixture will hybridize with the target gene. These oligonucleotide probes are at least 17-mers because shorter degenerate oligonucleotides might hybridize with sequences unrelated to the target sequence.

A piece of DNA from the corresponding gene in a related organism can also be used as a probe in screening a library for a particular gene. Such probes are termed **heterologous probes** because they are not derived from the homologous (same) organism. Problems arise if a complete eukaryotic gene is the cloning target; eukaryotic genes can be tens or even hundreds of kilobase pairs in size. Genes of this size are fragmented in most cloning procedures. Thus, the DNA identified by the probe may represent a clone that carries only part of the desired gene. However, most cloning strategies are based on a partial digestion of the genomic DNA, a technique that generates an overlapping set of genomic fragments. This being so, DNA segments from the ends of the identified clone can now be used to probe the library for clones carrying DNA sequences that flanked the original isolate in the genome. Repeating this process ultimately yields the complete gene among a subset of overlapping clones.

12.2d PCR Is Used to Clone and Amplify Specific Genes

Provided sequence information is available, **polymerase chain reaction**, or **PCR**, is a technique for identifying and dramatically amplifying the amount of a specific DNA segment, and PCR amplification is an effective, indeed the preferred, cloning strategy. PCR relies on DNA polymerase to carry out multiple rounds of DNA synthesis. A preparation of denatured DNA containing the desired segment (such as total genomic DNA) serves as a template for DNA polymerase, and two specific oligonucleotides serve as primers (as shown in Figure 12.9). The design of appropriate primers for the DNA polymerase is key to PCR, because these primers must base-pair with the template adjacent to the DNA sequence of interest (see Figure 11.2). These primers are designed to be complementary to the two 3'-ends of the specific DNA segment to be amplified; primers are added in excess amounts of 1000 times or greater (Figure 12.9). They prime the DNA polymerase-catalyzed synthesis of the two complementary strands of the desired segment, effectively doubling its concentration in the solution. Then the DNA is heated to dissociate the DNA duplexes,

Figure 12.9 Polymerase chain reaction (PCR).

followed by cooling so that more primers can bind to both the newly formed and the old strands. Another cycle of DNA synthesis follows. The protocol has been automated by carrying out the reaction in **thermal cyclers** that alternately heat the reaction mixture to 95°C to dissociate the DNA, followed by cooling, annealing of primers, and another round of DNA synthesis. The use of heat-stable DNA polymerases from thermophilic bacteria (such as the *Taq* DNA polymerase from *Thermus aquaticus*) makes it unnecessary to add fresh enzyme for each round of synthesis. Because the amount of target DNA theoretically doubles each

Critical Developments in Biochemistry

Identifying Specific DNA Sequences by Southern Blotting (Southern Hybridization)

As discussed, any given DNA fragment is unique solely by virtue of its specific nucleotide sequence. The only practical way to find a particular DNA segment among a vast population of different DNA fragments (such as you might find in genomic DNA preparations) is to exploit its sequence specificity to identify it. In 1975, E. M. Southern invented a technique capable of doing just that.

Electrophoresis

Southern first fractionated a population of DNA fragments according to size by gel electrophoresis (see step 2 in figure). The electrophoretic mobility of a nucleic acid is inversely proportional to its molecular mass. Polyacrylamide gels are suitable for the separation of nucleic acids of 25 to 2000 bp. Agarose gels are better if the DNA fragments range up to 10 times this size. Most preparations of genomic DNA show a broad spectrum of sizes, from less than 1 kbp to more than 20 kbp. Typically, no discrete-size fragments are evident following electrophoresis, just a smear of DNA throughout the gel.

Blotting

Once the fragments have been separated by electrophoresis (step 3), the gel is soaked in alkali to convert the duplex DNA into single-stranded DNA. After adjusting the pH of the gel to neutral, a sheet of absorbent material is placed over the gel, and salt solution is drawn through the gel by electrophoresis in a direction perpendicular to the direction of the first electrophoresis (step 4). The salt

solution carries the DNA to the absorbent sheet, which binds the ssDNA molecules very tightly, effectively immobilizing them on the sheet. The distribution pattern of separated DNA fragments is maintained when the ssDNA molecules bind to the absorbent sheet (step 5 in figure). The sheet is dried and then incubated with a solution containing protein (serum albumin, for example) and/or a detergent such as sodium dodecylsulfate to saturate any remaining binding sites for DNA on the sheet, so no more DNA can bind nonspecifically.

Hybridization

To detect a particular DNA within the electrophoretic smear of countless DNA fragments, the sheet is exposed to a specific probe (step 6 in figure). A probe is usually a ssDNA of defined sequence that carries a fluorescent tag or some other easily detectable marker. The sequence of the probe is designed to be complementary to the *target* DNA fragment. The probe DNA base pairs with the target DNA, revealing its position on the sheet (step 7 in figure). Southern's procedure has been extended to the identification of specific RNA and protein molecules: In a play on Southern's name, the identification of particular RNAs following separation by gel electrophoresis, blotting, and probe hybridization is called **Northern blotting**. The analogous technique for identifying protein molecules is termed **Western blotting**. In Western blotting, the probe of choice is usually an antibody specific for the target protein.

The Southern blotting technique involves the transfer of electrophoretically separated DNA fragments to an absorbent sheet and subsequent detection of specific DNA sequences, using labeled, single-stranded probe DNA that hybridizes with target DNA sequences complementary to it. The location of these target sequences is revealed by the labeled probe.

round, 25 rounds would increase its concentration about 33 million times. In practice, the increase is actually more like a million times, which is more than ample for gene isolation. Thus, starting with a tiny amount of total genomic DNA, a particular sequence can be produced in quantity in a few hours. Because DNA from a single cell can be used as a template, the technique has enormous potential for the clinical diagnosis of infectious diseases and genetic abnormalities. With PCR techniques, DNA from a single hair or sperm can be analyzed to identify particular individuals in criminal cases without ambiguity.

12.2e cDNA Libraries Are DNA Libraries Prepared from mRNA

Complementary DNAs (cDNAs) are DNA molecules copied from mRNA templates. cDNA libraries are constructed by synthesizing cDNA from purified cellular mRNA. These libraries present an alternative strategy for gene isolation, especially eukaryotic genes. Because most eukaryotic mRNAs carry 3'-poly(A) tails, mRNA can be selectively isolated from preparations of total cellular RNA by oligo(dT)-cellulose chromatography (Figure 12.10). DNA copies of the purified mRNAs are synthesized by first annealing short oligo (dT) chains to the poly(A) tails. These oligo(dT) chains serve as primers for reverse transcriptase-driven synthesis of DNA (Figure 12.11). **Reverse transcriptase** is an enzyme that synthesizes a DNA strand, copying RNA as the template. DNA polymerase is then used to copy the DNA strand and form a double-stranded (duplex DNA) molecule. Linkers are then added to the DNA duplexes rendered from the mRNA templates, and the cDNAs are cloned into a suitable vector to create a cDNA library.

RT-PCR (reverse transcriptase-PCR), a variation on the basic PCR method, is useful for cloning the gene that encodes a specific mRNA. Reverse transcriptase (RT) is used to synthesize a cDNA strand complementary with the RNA, and this cDNA serves as the template for further cycles of PCR. This amplified DNA is then used to probe genomic libraries to isolate the gene of interest.

Because different cell types in eukaryotic organisms express selected subsets of genes, RNA preparations from cells or tissues in which genes of interest are selectively transcribed are enriched for the desired mRNAs. cDNA libraries prepared from such mRNA are representative of the pattern and extent of gene expression that uniquely define particular kinds of differentiated cells. cDNA libraries of many normal and abnormal human cell types are commercially available, including cDNA libraries of tumor cells. Comparison of

Figure 12.10 Isolation of eukaryotic mRNA via oligo(dT)-cellulose chromatography. **(a)** In the presence of 0.5 M NaCl, the poly(A) tails of eukaryotic mRNA anneal with short oligo(dT) chains covalently attached to an insoluble chromatographic matrix such as cellulose. Other RNAs, such as rRNA (green), pass right through the chromatography column. **(b)** The column is washed with more 0.5 M NaCl to remove residual contaminants. **(c)** Then the poly(A) mRNA (red) is recovered by washing the column with water because the base pairs formed between the poly(A) tails of the mRNA and the oligo(dT) chains are unstable in solutions of low ionic strength.

Figure 12.11 Reverse transcriptase-driven synthesis of cDNA from oligo(dT) primers annealed to the poly(A) tails of purified eukaryotic mRNA. **(a)** Oligo(dT) chains serve as primers for synthesis of a DNA copy of the mRNA by reverse transcriptase. Following completion of first-strand cDNA synthesis by reverse transcriptase, RNase H and DNA polymerase are added. **(b)** RNase H specifically digests RNA strands in DNA;RNA hybrid duplexes. DNA polymerase copies the first-strand cDNA, using as primers the residual RNA segments after RNase H has created nicks and gaps. **(c)** DNA polymerase has a 5'→3' exonuclease activity that removes the residual RNA as it fills in with DNA. The nicks remaining in the second-strand DNA are sealed by DNA ligase. **(d)** The nicks remaining in the second-strand DNA are sealed by DNA ligase, yielding duplex cDNA. **(e)** EcoRI adapters with 5'-overhangs are then ligated onto the cDNA duplexes using phage T4 DNA ligase to create EcoRI-ended cDNA for insertion into a cloning vector.

cDNA libraries, from normal and abnormal cells in conjunction with two-dimensional gel electrophoretic analysis (see A Deeper Look: Techniques Used in Protein Purification in Chapter 5) of the proteins produced is a useful strategy in clinical medicine to understand disease mechanisms.

Expressed Sequence Tags When a cDNA library is prepared from the mRNAs synthesized in a particular cell type under certain conditions, these cDNAs represent the nucleotide sequences (genes) that have been expressed in this cell type under these conditions. **Expressed sequence tags (ESTs)** are relatively short (~200 nucleotides or so) sequences obtained by determining a portion of the nucleotide sequence for each insert in randomly selected cDNAs. An EST represents part of a gene that is being expressed. Probes derived from ESTs can be labeled and used in hybridization experiments to identify which genes in a genomic library are being expressed in the cell. For example, labeled ESTs can be hybridized to a *gene chip* (see following discussion).

12.2f DNA Microarrays (Gene Chips) Are Arrays of Different Oligonucleotides Immobilized on a Chip

Robotic methods can be used to synthesize combinatorial libraries of DNA oligonucleotides directly on a solid support, such that the completed library is a two-dimensional array of different oligonucleotides (as discussed in the Critical Developments in Biochemistry box on combinatorial libraries earlier in this section). Synthesis is performed by phosphoramidite chemistry (Figure 11.31) adapted into a photochemical process that can be controlled by light. Computer-controlled masking of the light allows the photochemical reaction to take place at some spots in the two-dimensional array of growing oligonucleotides and not at others, so each spot on the array is a population of identical oligonucleotides of unique sequence. The final products of such procedures are referred to as gene chips because the oligonucleotide sequences synthesized upon the chip represent the sequences of chosen genes. Typically, the oligonucleotides are up to 25 nucleotides long (there are more than 10^{15} possible sequence arrangements for 25-mers made from four bases), and as many as 1.3 million different oligonucleotides can be arrayed on a chip 1 cm square. The oligonucleotides on such gene chips are used as the probes in a hybridization experiment to reveal gene expression patterns. Figure 12.12 shows one design for gene chip analysis of gene expression.

Figure 12.12 Gene chips (DNA microarrays) in the analysis of gene expression. Here is one of many analytical possibilities based on DNA microarray technology:

(a) Random or sequence-specific oligonucleotide arrays can be synthesized in situ on a small glass surface (chip), employing phosphoramidite chemistry (Figure 11.31), using laserjet printing to deliver microdrops of deoxynucleotides with photo-labile or electrochemically sensitive blocking groups that can be removed after each cycle of nucleotide addition. Alternatively, gene segments (for example, ESTs) are isolated and amplified by PCR (see Figure 12.9), and the PCR products are robotically printed onto coated glass microscope slides to create a gene chip. The gene chip usually is considered the probe in a target:probe screening experiment. **(b)** Target preparation: Total RNA from two sets of cell treatments (control and test treatment) are isolated, and cDNA is produced from the two batches of RNA via reverse transcriptase. During cDNA production, the control is labeled with a specific fluorescent marker (green, for example) and the test treatment is labeled with a different fluorescent marker (red, for example), so the wavelength of fluorescence allows discrimination between the two different sets of cDNAs. **(c)** The two batches of labeled cDNA are pooled and hybridized to the gene chip. **(d)** Laser excitation of the hybridized gene chip with light of appropriate wavelength allows collection of data indicating the intensities of fluorescence, and hence the degree of hybridization of the two different probes with the gene chips. Because the location of genes on the gene chip is known, which genes are expressed (or not) and the degree to which they are expressed is revealed by the fluorescent patterns. (Adapted from Figure 1 in Duggan, D. J., et al., 1999. Expression profiling using cDNA microarrays. *Nature Genetics* 21 supplement:10–14.)

Figure 12.13 Expression vectors carrying the promoter recognized by the RNA polymerase of bacteriophage SP6 are useful for the production of multiple RNA copies of any DNA inserted at the polylinker. Before transcription is initiated, the circular expression vector is linearized by a single cleavage at or near the end of the insert so that transcription terminates at a fixed point.

12.3 Can the Genes in Libraries Be Transcribed and Translated?

Libraries of cloned genes are excellent resources for the investigation of gene regulation and analysis of the proteins encoded by the genes. To carry out such studies, these genes must be expressed via the processes of transcription and translation.

12.3a Expression Vectors Are Engineered So That the RNA or Protein Products of Cloned Genes Can Be Synthesized

Expression vectors are engineered so that any cloned insert can be transcribed into RNA, and, in many instances, even translated into protein. cDNA expression libraries can be constructed in specially designed vectors. Proteins encoded by the various cDNA clones within such expression libraries can be synthesized in the host cells, and if suitable assays are available to identify a particular protein, its corresponding cDNA clone can be identified and isolated. Expression vectors designed for RNA expression or protein expression, or both, are available.

RNA Expression A vector for in vitro expression of DNA inserts as RNA transcripts can be constructed by putting a highly efficient promoter adjacent to a versatile cloning site. Figure 12.13 depicts a typical expression vector. Linearized recombinant vector DNA is transcribed in vitro using SP6 RNA polymerase. Large amounts of RNA product can be obtained in this manner; if radioactive or fluorescent-labeled ribonucleotides are used as substrates, labeled RNA molecules useful as probes are made.

Measuring the Abundance of an mRNA by RT-qPCR Real-time quantitative polymerase chain reaction (RT-qPCR) is a technique for directly determining mRNA expression without cloning its gene.¹ RT-qPCR measures the abundance of a particular mRNA within the total RNA isolated from a particular cell type. Reverse transcriptase is used to synthesize cDNA copies of the mRNAs within the sample, and then specific primers are used to amplify the amount of the target mRNA by PCR, using DNA polymerase. The amount of dsDNA that accumulates during each PCR cycle is determined as it is formed (that is, in real time) by fluorescence, either through intercalation of fluorescent dyes (see Figure 11.15) or release of fluorescent tags from mRNA-specific probes as DNA polymerase copies the templates. Plots of the fluorescence intensity versus PCR cycle provide information about the amount of the target mRNA in the original total RNA sample (Figure 12.14).

Protein Expression Because cDNAs are DNA copies of mRNAs, cDNAs are uninterrupted copies of the exons of expressed genes. Because cDNAs lack introns, it is feasible to express these cDNA versions of eukaryotic genes in prokaryotic hosts that cannot process the complex primary transcripts of eukaryotic genes. To express a eukaryotic protein in *E. coli*, the eukaryotic cDNA must be cloned into an *expression vector* that contains regulatory signals for both transcription and translation. Accordingly, a *promoter* where RNA polymerase initiates transcription as well as a *ribosome-binding site* to facilitate translation are engineered into the vector just upstream from the restriction site for inserting foreign DNA. The AUG initiation codon that specifies the first amino acid in the protein (the *translation start site*) is contributed by the insert (Figure 12.15).

Some expression vectors have strong promoters that drive the synthesis of foreign proteins to levels equal to 30% or more of total *E. coli* cellular protein. An example is the hybrid promoter, p_{tac} , which was created by fusing part of the promoter for the *E. coli* genes encoding the enzymes of lactose metabolism (the *lac* promoter) with

¹RT is a bit ambiguous in reference to PCR. It can connote “reverse transcriptase” or “real-time,” depending on context.

Figure 12.14 RT-qPCR amplification plots of target mRNA, as relative fluorescence versus number of PCR cycles. The different curves equate to differing mRNA abundance in the sample, with the number of mRNA copies (10^3 – 10^7) indicated. (Adapted from Figure 1 in Gibson, U. E., Heid, C. A., and Williams, P. M., 1996. A novel method for real time quantitative PCR. *Genome Research* 6:995–1001.)

Figure 12.15 A typical expression-cloning vector. (Adapted from Fig. 19-19, in Watson, J. D., et al., *Molecular Biology of the Gene* 4/e. Menlo Park, Calif.: Benjamin/Cummings, 1987.)

part of the promoter for the genes encoding the enzymes of tryptophan biosynthesis (the *trp* promoter) (Figure 12.16). In cells carrying p_{tac} expression vectors, the p_{tac} promoter is not induced to drive transcription of the foreign insert until the cells are exposed to *inducers* that lead to its activation. Analogs of lactose (a β -galactoside) such as *isopropyl- β -thiogalactoside*, or *IPTG*, are excellent inducers of p_{tac} . Thus, expression of the foreign protein is easily controlled.

A widely used protein expression system is based on the pET plasmid. Transcription of the cloned gene insert is under the control of the bacteriophage T7 RNA polymerase promoter in pET. This promoter is not recognized by the *E. coli* RNA polymerase, so transcription can only occur if the T7 RNA polymerase is present in host cells. Host *E. coli* cells are engineered so that the T7 RNA polymerase gene is inserted in the host chromosome under the control of the *lac* promoter. IPTG induction triggers T7 RNA polymerase production and subsequent transcription and translation of the pET insert. The bacteriophage T7 RNA polymerase is so active that most of the host cell's resources are directed into protein expression and levels of expressed protein approach 50% of total cellular protein.

The bacterial production of valuable eukaryotic proteins represents one of the most important uses of recombinant DNA technology. For example, human insulin for the clinical treatment of diabetes is now produced in bacteria.

Figure 12.16 A p_{tac} protein expression vector contains the hybrid promoter p_{tac} derived from fusion of the *lac* and *trp* promoters. Isopropyl- β -D-thiogalactoside, or IPTG, induces expression from p_{tac} .

Analogous systems for expression of foreign genes in eukaryotic cells include vectors carrying promoter elements derived from mammalian viruses, such as *simian virus 40 (SV40)*, the *Epstein–Barr virus*, and the human *cytomegalovirus (CMV)*. A system for high-level expression of foreign genes uses insect cells infected with the *baculovirus* expression vector. **Baculoviruses** infect *lepidopteran* insects (butterflies and moths). In engineered baculovirus vectors, the foreign gene is cloned downstream of the promoter for **polyhedrin**, a major viral-encoded structural protein, and the recombinant vector is incorporated into insect cells grown in culture. Expression from the polyhedrin promoter can lead to the accumulation of the foreign gene product to levels as high as 500 mg/L.

Technologies for the expression of recombinant proteins in mammalian cell cultures are also commercially available. These technologies have the advantage that the unique post-translational modifications of proteins (such as glycosylation; see Chapters 5, 7, and 31) seen in mammalian cells take place *in vivo* so that the expressed protein is produced in its naturally occurring form.

Fusion Protein Expression Some expression vectors carry cDNA inserts cloned directly into the coding sequence of a vector-borne protein-coding gene (Figure 12.17). Translation of the recombinant sequence leads to synthesis of a *hybrid protein* or *fusion protein*. The N-terminal region of the fused protein represents amino acid sequences encoded in the vector, whereas the remainder of the protein is encoded by the foreign insert. Keep in mind that the triplet codon sequence within the cloned insert must be in the same reading frame with codons contributed by the vector sequences to make the right protein. Furthermore, adding an N-terminal signal sequence that targets the hybrid protein for secretion from the cell simplifies recovery of the fusion protein. A variety of gene fusion systems have been developed to facilitate isolation of a specific protein encoded by a cloned insert. The isolation procedures are based on affinity chromatography purification of the fusion protein through exploitation of the unique ligand-binding properties of the vector-encoded protein (Table 12.1).

Screening cDNA Expression Libraries with Antibodies Antibodies that specifically cross-react with a particular protein of interest are often available. If so, these antibodies can be used to screen a cDNA expression library to identify and isolate cDNA clones encoding the protein. The cDNA library is introduced into host bacteria, which are plated out and grown overnight, as in the colony hybridization scheme previously described. DNA-binding nylon membranes are placed on the plates to obtain a replica of the bacterial colonies. The nylon membrane is then incubated under conditions that induce protein synthesis from the cloned cDNA inserts, and the cells are treated to release the synthesized protein. The synthesized protein binds tightly to the nylon membrane, which can then be incubated with the specific antibody. Binding of the

Figure 12.17 A typical expression vector for the synthesis of a hybrid protein. The cloning site is located at the end of the coding region for the protein β -galactosidase. Insertion of foreign DNAs at this site fuses the foreign sequence to the β -galactosidase coding region (the *lacZ* gene). IPTG induces the transcription of the *lacZ* gene from its promoter p_{lac} , causing expression of the fusion protein. (Adapted from Figure 2, R  ther, U., and M  ller-Hill, B., 1983. *EMBO Journal* 2:1791–1794.)

Table 12.1 Gene Fusion Systems for Isolation of Cloned Fusion Proteins

Fusion Protein	Secreted?*	Affinity Ligand
β -Galactosidase	No	π -Aminophenyl- β -D-thiogalactoside (APTG)
Protein A	Yes	Immunoglobulin G (IgG)
FLAG peptide (DYKDDDDK)	Yes	FLAG-specific monoclonal antibody
Streptavidin	Yes	Biotin
Glutathione-S-transferase (GST)	No	Glutathione
Maltose-binding protein (MBP)	Yes	Starch
Hexahistidine tag	No	Nickel or cobalt
Hemagglutinin (HA) peptide	No	HA-peptide antibody

*This indicates whether combined secretion–fusion gene systems have led to secretion of the protein product from the cells, which simplifies its isolation and purification.

antibody to its target protein product reveals the position of any cDNA clones expressing the protein, and these clones can be recovered from the original plate. Like other libraries, expression libraries can be screened with oligonucleotide probes, too.

12.3b Reporter Gene Constructs Are Chimeric DNA Molecules Composed of Gene Regulatory Sequences Positioned Next to an Easily Expressible Gene Product

Potential regulatory regions of genes (such as promoters) can be investigated by placing these regulatory sequences into plasmids upstream of a gene, called a **reporter gene**, whose expression is easy to measure. Such chimeric plasmids are then introduced into cells of choice (including eukaryotic cells) to assess the potential function of the regulatory sequences because expression of the reporter gene serves as a report on the effectiveness of the regulatory element. A number of different genes have been used as reporter genes. A reporter gene with many inherent advantages is that encoding the **green fluorescent protein** (or **GFP**), described in Chapter 4. Unlike the protein expressed by other reporter gene systems, GFP does not require any substrate to measure its activity, nor is it dependent on any cofactor or prosthetic group. Detection of GFP requires only irradiation with near-UV or blue light (400 nm light is optimal), and the green fluorescence (light of 500 nm) that results is easily observed with the naked eye, although it can also be measured precisely with a fluorometer. Figure 12.18 demonstrates the use of the genes encoding GFP and mCherry, a similar fluorescent protein, as reporter genes.

Figure 12.18 Green fluorescent protein (GFP) and Cherry fluorescent protein (mCherry) as reporter genes. In this experiment, GFP expression is under the control of the promoter for the *Danio rerio* (zebrafish) *hb9* gene. *Hb9* encodes a homeobox protein (Hb9) expressed specifically in motor neurons. mCherry expression depends on the promoter for the zebrafish *nkx2.2a* gene. *Nkx2.2a* is another homeobox gene (encoding Nkx2.2a protein) expressed specifically in glia. Glia are non-neuronal cells that support and maintain neurons. (Bottom) Green fluorescence labels motor neuron cell bodies and projections, specifically in motor nerves. mCherry expression labels glia in both the brain and spinal cord. mCherry is a red fluorescent protein encoded by a gene found in *Discosoma* species, which are soft corals, not jellyfish. 12.3c Specific Protein–Protein Interactions Can Be Identified Using the Yeast Two-Hybrid System

Specific interactions between proteins (**protein–protein interactions**) lie at the heart of many essential biological processes. One method to identify specific protein–protein interactions *in vivo* is through the expression of a reporter gene whose transcription is dependent on a functional transcriptional activator, the *GAL4* protein. The *GAL4* protein consists of two domains: a **DNA-binding (or DB) domain** and a **transcriptional activation (or TA) domain**. Even if expressed as separate proteins, these two domains will still work, provided they can be brought together. The method depends on two separate plasmids encoding two hybrid proteins, one consisting of the *GAL4* DB domain fused to protein X and the other consisting of the *GAL4* TA domain fused to protein Y (Figure 12.19). If proteins X and Y interact in a specific protein–protein interaction, the *GAL4* DB and TA domains are brought together so that transcription of a reporter gene driven by the *GAL4* promoter can take place (Figure 12.19). Protein X, fused to the *GAL4*-DNA-binding domain (DB), serves as the bait to fish for the protein Y target and its fused *GAL4* TA domain. This method can be used to screen cells for protein targets that interact specifically with a particular bait protein. To do so, cDNAs encoding proteins from the cells of interest are inserted into the TA-containing plasmid to create fusions of the cDNA coding sequences with the *GAL4* TA domain coding sequences, so a fusion protein library is expressed. Identification of a target of the bait protein by this method also directly yields a cDNA version of the gene encoding the target protein. Two-hybrid systems to identify protein–protein interactions in bacteria and in mammalian cells are available.

Identifying Protein–Protein Interactions Through Immunoprecipitation If antibodies against one protein of a multiprotein complex are available, the entire complex can be immunoprecipitated and its composition analyzed. Attachment of such antibodies to glass or agarose beads, which easily sediment in a centrifuge, makes recovery of the complex very simple. Because antibodies against it are commercially available, the hemagglutinin (HA) peptide sequence YPYDVPDYA is a useful protein fusion tag, not only for fusion protein purification (Table 12.1), but also for analysis of protein–protein interactions. Expressing an HA-tagged protein *in vivo*, followed by immunoprecipitation, allows the isolation of protein complexes of which the HA-tagged protein is a member. The other members of the complex can then be identified to establish the various interacting partners within the multiprotein complex.

ChIP-Seq—Isolating Specific DNA Sequences Through Their Interactions with Proteins ChIP-Seq is an acronym for chromatin immunoprecipitation-DNA sequencing, a technique in which an antibody against a specific DNA-binding protein is used to immunoprecipitate complexes from fragmented chromatin preparations that contain the specific protein and any DNA sequence associated with it. Recovery of the DNA from these immunoprecipitated complexes followed by massively parallel DNA sequencing (see Section 11.1) reveals a collection of target DNA sites for the protein of

Figure 12.19 The yeast two-hybrid system for identifying protein–protein interactions. If proteins X and Y interact, the *lacZ* reporter gene is expressed. Cells expressing *lacZ* exhibit β -galactosidase activity.

interest. Thus, the sequences bound by any DNA-binding protein can be precisely identified and mapped globally according to their location within the genome. The results of these studies can be used to determine how specific DNA-binding proteins affect the phenotype of the organism.

12.3d In Vitro Mutagenesis—Introducing Changes into Expressed Proteins

The advent of recombinant DNA technology has made it possible to clone genes, manipulate them *in vitro*, and express them in a variety of cell types under various conditions. The function of any protein is ultimately dependent on its amino acid sequence, which in turn can be traced to the nucleotide sequence of its gene. The introduction of purposeful changes in the nucleotide sequence of a cloned gene represents an ideal way to make specific structural changes in a protein. The effects of these changes on the protein's function can then be studied. Such changes constitute *mutations* introduced *in vitro* into the gene. *In vitro* **mutagenesis** makes it possible to alter the nucleotide sequence of a cloned gene systematically, as opposed to the chance occurrence of mutations in natural genes.

One technique for *in vitro* mutagenesis is **PCR-based mutagenesis**. Mutant primers are added to a PCR reaction in which the gene (or segment of a gene) is undergoing amplification. The *mutant primers* are primers whose sequence has been specifically altered to introduce a directed change at a particular place in the nucleotide sequence of the gene being amplified (Figure 12.20). Mutant versions of the gene can then be cloned and expressed to determine any effects of the mutation on the function of the gene product. Alternatively, precise manipulation and revision of any gene's nucleotide sequence can be achieved using the CRISPR/Cas9 editing system described in Section 12.5.

12.4 | How Is RNA Interference Used to Reveal the Function of Genes?

RNA interference (**RNAi**) has emerged as a useful method in eukaryotic gene inactivation. RNAi leads to targeted destruction of a selected gene's RNA transcript. The consequences that follow the loss of gene function reveal the role of the gene product in cell metabolism. Inactivation of gene expression by RNAi is sometimes referred to as **gene knockdown**. Gene knockdown is a term that contrasts the method with **gene knockout**, a procedure that inactivates a gene by disrupting its nucleotide sequence.

Procedures for silencing gene expression via RNAi depend on the introduction of double-stranded RNA (dsRNA) molecules into target cells by transfection, viral infection, or other means. One strand of the dsRNA is designed to be an antisense RNA, in that its nucleotide sequence is complementary to the RNA transcript of the gene selected for silencing. An ATP-dependent endogenous nucleoprotein complex known as **Dicer** processes the dsRNA. Dicer is an RNase III family member that catalyzes endonucleolytic cleavage of both strands of dsRNA molecules to produce a double-stranded **small interfering RNA (siRNA)** 21 to 23 nucleotides long with 2-nucleotide-long 3'-overhangs on each strand (Figure 12.21). The siRNA is then passed to another protein complex known as **RNA-induced silencing complex (RISC)**. In an ATP-dependent process, RISC unwinds the double-stranded siRNA and selects the antisense strand, which is referred to as the **guide strand**. The other strand, referred to as the **passenger strand**, is discarded. RISC pairs the single-stranded guide strand with a complementary region on the targeted gene transcript. RISC then carries out its slicer function by cleaving the RNA transcript between nucleotides 10 and 11 of the mRNA region that is base-paired with the guide strand. Such cleavage prevents expression of the product encoded by the mRNA. The guide strand remains associated with RISC, and RISC can use it for multiple cycles of mRNA cleavage and post-transcriptional gene silencing.

Figure 12.20 One method of PCR-based site-directed mutagenesis. (1) Template DNA strands are separated and amplified by PCR using mutagenic primers (represented as bent arrows) whose sequences introduce a single base substitution at site X (and its complementary base X'); thus creating the desired amino acid change in the protein encoded by the gene). Ideally, the mutagenic primers also introduce a unique restriction site into the plasmid that was not present before. (2) Following many cycles of PCR, the DNA product can be used to transform *E. coli* cells. (3) The plasmid DNA can be isolated and screened for the presence of the mutation by screening for the presence of the unique restriction site by restriction endonuclease cleavage. For example, the nucleotide sequence GGATCT within a gene codes for amino acid residues Gly-Ser. Using mutagenic primers of nucleotide sequence AGATCT (and its complement AGATCT) changes the amino acid sequence from Gly-Ser to Arg-Ser and creates a *Bgl*II restriction site (see Table 10.2). Gene expression of the isolated mutant plasmid in *E. coli* allows recovery and analysis of the mutant protein.

Figure 12.21 Gene knockdown by RNAi.

The dsRNA is processed by Dicer, which cleaves both strands of the dsRNA to form an siRNA, a ~20-nucleotide dsRNA with 3'-overhangs. A helicase activity associated with Dicer unwinds the siRNA, and the guide strand is delivered to the RISC protein complex. An Argonaute protein family member (Ago) is the catalytic subunit of RISC. Ago has a dsRNA-binding domain that brings together the guide strand and a complementary nucleotide sequence on the targeted gene transcript. Ago also has a RNase H-type catalytic domain that cleaves the gene transcript, rendering it incapable of translation by ribosomes. This RNase H activity of Ago is whimsically referred to as the slicer function in RNAi.

A clever innovation in RNAi is to introduce the silencing RNA in the form of a short hairpin, or **shRNA**. A 47-bp DNA sequence is created in which the first 19 nucleotides are complementary to the target mRNA. Within the larger shRNA, this 19 base segment is separated by a short, nine nucleotide spacer from the reverse complement of the same 19-bp sequence, so that the DNA encodes a transcript that will fold back on itself to form a 19-bp double-stranded stem-loop RNA structure. DNA encoding such 47-bp sequences can be introduced into plasmids and expressed in target cells. Or, lipid nanoparticles, like the ones used in the mRNA viruses developed to inoculate against SARS-CoV-2, can deliver shRNAs to recipient cells. Such shRNA transcripts are recognized by Dicer and processed to generate a gene-specific siRNA.

12.5 | Gene Therapy: Is It Possible for Scientists to Alter or Rewrite the Genome of an Organism?

Recombinant DNA technology is a powerful tool for the genetic modification of organisms. The strategies and methodologies described in this chapter are only an overview of the repertoire of experimental approaches that have been devised by molecular biologists to manipulate DNA and the information encoded in it. The enormous success of recombinant DNA technology means that the molecular biologist's task in searching genomes for genes is now akin to that of a lexicographer compiling a dictionary, a dictionary in which the letters (the nucleotide sequences) spell out not words but rather genes and what they mean. Molecular biologists have no index or alphabetic arrangement to serve as a guide through the vast volume of information in a genome; nevertheless, this information and its organization are rapidly being disclosed by the imaginative efforts and diligence of these scientists and their growing arsenal of analytical schemes.

Using recombinant DNA technology, it is now possible to engineer at will the heredity (or genetic makeup) of organisms for desired ends. The commercial production of therapeutic biomolecules in microbial cultures is already established (for example, the production of human insulin in quantity in *E. coli* cells). Agricultural crops with desired attributes, such as enhanced resistance to herbicides or elevated vitamin levels, are in cultivation. Transgenic mice are widely used as experimental animals to investigate models of human disease and physiology. Already, transgenic versions of domestic animals such as pigs, sheep, and even fish have been developed for human benefit. Perhaps most important, in an increasing number of instances, gene replacement therapy (or, more simply, gene therapy) and gene editing are being used to correct certain human genetic disorders.

12.5a Human Gene Therapy Can Repair Genetic Deficiencies

Human gene therapy seeks to repair the damage caused by a genetic deficiency through the introduction of a functional version of the defective gene. To achieve this end, a cloned variant of the gene must be incorporated into the organism in such a manner that it is expressed only at the proper time and only in appropriate cell types. Alternatively, the nucleotide sequence of an inactive or dysfunctional resident gene is edited to change it into one with normal function. Although such requirements impose serious technical and clinical challenges, successful human gene therapy is now a reality. Hundreds of gene therapies have received approval for use in human patients, including the introduction of gene constructs into patients. Among these are constructs designed to cure ADA- SCID (severe combined immunodeficiency due to adenosine deaminase [ADA] deficiency), neuroblastoma, cystic fibrosis, or to treat cancer through the expression of the E1A and p53 tumor suppressor genes. Insertion of the CD19 surface antigen gene into a patient's T lymphocytes has been used to create the Kymriah therapy for treatment of lymphoma and leukemia. Figure 12.22 shows some of the possible routes for introduction of functional genes into human cells. A reliable methodology to deliver a functional gene into any desired target cell type is not yet available.

Figure 12.22 Various methods to carry out gene therapy on human cells. Viruses gain entry by interaction with membrane receptors. Liposomes are spherical vesicles containing therapeutic genes. Their membranes are composed of phospholipid bilayers designed to fuse with the plasma membrane of target cells. Cationic polymers are a non-viral way to deliver DNA to cells. Cationic polymers form nanoscale complexes with nucleic acids and deliver them across cell membranes. They act by neutralizing the negative charge on DNA or RNA. (Adapted from Figure 1 in Goswami, R., et al., 2019. Gene therapy leaves a vicious cycle. *Frontiers in Oncology* 9:297, DOI:10.3389/fonc.2019.00297.)

12.5b Viruses as Vectors in Human Gene Therapy

A basic strategy in human gene therapy involves the incorporation of a functional gene into target cells in one of two ways. The gene is typically in the form of an expression cassette consisting of a cDNA version of the gene downstream from a promoter that will drive expression of the gene. One way to incorporate the cassette, the *ex vivo* route, is to introduce a vector carrying the expression cassette into cells that have been isolated from a patient and cultured in the laboratory. The modified cells are then reintroduced into the patient. The other way involves the direct incorporation of the gene by treating the patient with a viral vector carrying the expression cassette. Retroviruses are commonly used in gene therapy. Retroviruses are RNA viruses that replicate their RNA genome by first making a DNA intermediate. Because retroviruses can transfer their genetic information directly into the genome of host cells, they can be used for permanent modification of host cells *ex vivo*.

In 2000, scientists at the Pasteur Institute in Paris used a retrovirus-based *ex vivo* approach to successfully treat infants with X-linked severe combined immunodeficiency (X-linked SCID). X-linked SCID occurs almost exclusively in males. Boys with X-linked SCID lack an effective γ c cytokine receptor. This receptor is necessary to produce functional lymphocytes, key cells in the immune response. Without treatment, males with X-linked SCID seldom survive beyond infancy. Gene therapy was used to deliver a functional γ c cytokine receptor subunit gene to stem cells harvested from the infants. Transformed stem cells were reintroduced into the patients, who were then able to produce functional lymphocytes and lead normal lives. This achievement represented the first successful outcome in human gene therapy. Unfortunately, several patients developed leukemia, apparently due to the chance insertion of the gene into the genome at places that altered the expression of nearby cancer-causing genes. Alternative, safer strategies for X-linked SCID are in clinical trials.

Successful human gene therapy has also been achieved using the *ex vivo* approach with recombinant lentiviral vectors (lentiviruses are also retroviruses and include HIV, the virus that causes AIDS). Two successes include: (1) the treatment of X-linked adrenoleukodystrophy (ALD, a fatal central nervous system disease) by the infection of hematopoietic stem cells (HSCs) with an HIV-1-derived lentiviral vector carrying a functional ALD gene; and (2) the treatment of β -thalassemia patients via the *ex vivo* transduction of their HSCs with a recombinant lentiviral vector carrying the gene for β -globin. (β -Thalassemics cannot produce functional β -globin chains, lack an effective population of red blood cells, and suffer life-threatening anemia.)

Adenovirus vectors, which can carry expression cassettes over 30 kbp in size, are an *in vivo* approach to human gene therapy. Adenoviruses are DNA viruses. Deletion of most of the 36-kbp adenovirus genome renders the adenovirus incapable of replication, and thus, viral infection. The recombinant adenoviruses enter the patient's cells via specific receptors on the target cell surface (Figure 12.23).

The transferred genetic information is expressed directly from the adenovirus recombinant DNA and is never incorporated into the host cell genome. An adenovirus vector formed the basis of the first commercially approved human gene therapy: Glybera. Direct intramuscular injection of the Glybera recombinant adenovirus was used to introduce a functional lipoprotein lipase gene into patients that lack one (such patients suffer from dramatically elevated levels of serum triglycerides, which can cause fatal pancreatitis). Adenovirus-based gene therapies have been developed for a variety of specific cancer types. Dozens of viral-based human gene therapy drugs are currently available in the global marketplace.

12.5c Genome Engineering

Instead of introducing foreign genes from other organisms into host cells to achieve some purpose, another approach is to directly alter an organism's genome, that is, change its nucleotide sequence at one or more specific sites. At one end of the scale, even a single nucleotide substitution could be made, for example, to reverse the mutation that causes sickle-cell anemia. Sickle-cell anemia is due to a single amino acid

Figure 12.23 Adenovirus-mediated delivery of therapeutic DNA. Infection of the target cell allows encapsulated therapeutic DNA to gain access to the interior through interactions with membrane protein receptors such as CAR and integrin. Once inside, the virus is released into the cytoplasm and enters the nucleus, where transcription of the gene, followed by translation of the mRNA leads to production of the therapeutic protein (which may or may not be delivered elsewhere through the blood.) (Adapted from Figure 2 in Goswami, R., et al., 2019. Gene therapy leaves a vicious cycle. *Frontiers in Oncology* 9:297, DOI:10.3389/fonc.2019.00297.)

change in the primary structure of the β -globin subunit of hemoglobin. This mutation occurs when a T is substituted for A as the middle base in the β -globin gene's sixth codon. This change transforms the sixth codon nucleotide sequence from GAG, which codes for glutamate, to GTG, which codes for valine. Changing that T back to A would restore full functionality to the β -globin gene. The ability to do such genome editing has the potential to correct deleterious mutations, which would be of great benefit in human gene therapy. CRISPR-Cas9 is a system that can be used to carry out such genome editing (see below).

At the other end of the genome engineering scale is the creation of entirely new genomes—the design and production of synthetic genomes that would direct novel organisms endowed with attributes desired by the creator. Although the complete *Mycobacterium mycoides* genome was chemically synthesized in 2010 (see the Critical Developments in Biochemistry box Synthetic Life in Chapter 1 and Figure 12.30), completely synthetic genomes that code for new life forms are confined to the future.

12.5d Genome Editing with CRISPR-Cas9

The challenge in genome editing is to make a direct change in the nucleotide sequence at a specific site within a genome, which may consist of billions of base pairs. One way to do this is to take advantage of the information presented by the nucleotide sequence around the selected site to target an editing system to the site. Once targeting is achieved, editing entails the replacement of the undesired nucleotide (or sequence) with the desired one.

Several targeting strategies have emerged, the most effective of which is CRISPR-Cas9, a simple two-component system. CRISPR-Cas9 can target and edit any nucleotide sequence in any genome. CRISPR is an acronym for clustered regularly interspaced short palindromic repeats. CRISPRs are a family of DNA repeats that are widespread among prokaryotic genomes. Cas9 (CRISPR-associated protein 9) is an RNA-guided endonuclease. That is, Cas9 is an RNA-binding enzyme that catalyzes the cleavage of dsDNA at a specific site determined by the nucleotide sequence of its bound RNA. The bound RNA acts as a guide; through complementary base-pairing, this guide RNA (gRNA, occasionally written as sgRNA for single guide RNA) can deliver the Cas9 endonuclease to any desired nucleotide sequence within a target DNA.

A Deeper Look

The Biological Role of CRISPR-Cas Systems: Adaptive immunity in Bacteria

The biological function of CRISPR-Cas systems is to serve as prokaryotic defense mechanisms against viruses and plasmids. Prior exposure of many bacterial or archaeal strains to foreign DNA endows these prokaryotes with the ability to fend off subsequent encounters from such intruders. Since the response depends on an earlier challenge, it is termed adaptive, and since the prokaryote is now immune to these agents, CRISPR/Cas systems provide adaptive immunity. How do they work?

The *cas* genes lie adjacent to the CRISPR loci and encode the Cas proteins, which are essential to adaptive immunity. *cas* is an acronym for CRISPR-associated. Each CRISPR locus contains a series of short DNA repeats (20–50 bp long) that are separated from one another by similarly-sized unique sequences to give a repeat-spacer-repeat pattern of organization. The spacers are derived from viral and plasmid DNA sequences formed when prokaryotic cells use Cas endonucleases to chop the foreign DNA of these infectious agents into short segments. Other Cas proteins then mediate the incorporation of these short segments into the prokaryotic genome as the spacers in CRISPRs.

Therefore, the spacer sequences are homologous to, and thus can base pair with, DNA sequences found in bacteriophages and plasmids which might infect the prokaryote. So, when the bacteria are exposed to a bacteriophage or virus they have previously seen, an adaptive immune response is triggered, such that the DNA of the invading pathogen is cleaved (and thus inactivated). For this to happen, an RNA is transcribed from the CRISPR locus and processed to yield a crRNA containing a repeat element and a spacer region that is homologous to, and thus can target, the invading foreign DNA. A second RNA, called the trans-activating CRISPR RNA, or tracrRNA, is required to bind the Cas endonuclease and deliver it to the target. The tracrRNA has a region of homology with the repeat element within the crRNA, and base-pairing between these two RNAs positions the Cas endonuclease at the proper site on the target DNA. The Cas endonuclease cleaves both strands of the foreign DNA, introducing a double-stranded break (DSB), which aborts its ability to infect the bacterial cell (figure). See Section 28.8 for a discussion of DSBs.

There are three types of CRISPR/Cas systems. The one used for genome editing, CRISPR/Cas9, is a type II system. CRISPR/Cas9 is a three-part system, consisting of a crRNA, a tracrRNA, and Cas9, the *cas9* gene-encoded endonuclease that catalyzes DSB

formation, as guided by crRNA base-pairing with foreign DNA. To simplify their use in genome editing, the crRNA and tracrRNA gene sequences have been fused to form a sgRNA (or single guide RNA) sequence that binds the Cas9 protein and positions it precisely on the target DNA, as determined by base-pairing between the spacer region of the gRNA and the target DNA sequence, which is usually referred to as the protospacer sequence because of its homology to the spacer (figure).

CRISPR-Cas9 action depends on a short nucleotide sequence known as the **protospacer adjacent motif (PAM)** about two to six nucleotides downstream (reading 5' to 3') of the DNA sequence targeted by the gRNA. The Cas endonuclease functions cut the DNA three to four nucleotides upstream of the PAM. Because different bacteria have different PAM specificities, CRISPR-Cas9 systems can be designed to cut any desired target sequence. For example, the *Streptococcus pyogenes* Cas9 recognizes a 5'-NGG-3' PAM (where "N" can be any nucleotide base). The *Staphylococcus aureus* Cas9 depends on an NGRRN PAM sequence (where R is any purine). Pairing the appropriate Cas9 with a gRNA directed at the desired DNA sequence allows virtually any DNA sequence to be edited. Cas9 will only act to cleave DNA when it finds the correct PAM sequence and the gRNA base-pairs with its target sequence.

Although the site-specific introduction of a double-stranded break (DSB) in DNA would not seem to offer any particular advantage in editing the DNA to change its nucleotide sequence to a more desirable one, it is actually very effective because cells are very adept at repairing DSBs.

At the site determined by the gRNA, Cas9 endonuclease acts to cleave both strands of the dsDNA. Since a gRNA of any desired nucleotide sequence is easily made, any DNA sequence is a legitimate target for Cas9 endonucleolytic cleavage (see Figure 12.24). The gRNA positions Cas9 precisely on the target DNA, as determined by base-pairing between a 20-nucleotide region of the gRNA (Figure 12.24). The Cas9 HNH nuclease domain cleaves the DNA strand complementary to the gRNA; the Cas9 RuvC nuclease domain cleaves the DNA strand that is not complementary to the gRNA (the DNA strand whose sequence matches the sequence of the gRNA).

There are two prominent DNA repair systems: nonhomologous end joining (NHEJ) and homology-directed repair (HDR) (Figure 12.24). In NHEJ, the two ends of a DSB are rejoined, and in the process, small insertions, deletions, and base substitutions occur. Assuming the somewhat random products of CRISPR-Cas9 cleavage followed by NHEJ can be screened for those repairs giving the hoped-for changes in nucleotide

Figure 12.24 CRISPR-Cas9 structural organization and catalytic function. Cas9 is shown in *blue*; the guide RNA in *orange*, with its 20-nucleotide DNA-targeting region in **bold**. Cas9 creates a double-stranded break (DSB) in the target DNA when its HNH endonuclease cleaves the DNA strand complementary to the gRNA, while its RuvC endonuclease cleaves the other DNA strand. The target DNA's PAM region is highlighted in *yellow*. Mammalian cells repair the DSB by either of two cellular pathways – the error-prone nonhomologous end-joining (NHEJ) pathway or by homology-directed repair, using an exogenous DNA as template. The molecular graphic shown here is *Streptococcus pyogenes* CRISPR-Cas9 in complex with sgRNA and double-stranded DNA primed for target DNA cleavage (the protein is *blue*, the RNA is *orange*, and the DNA is *green*); PDB id = 5F9R. (Adapted from Jiang, F., and Doudna, J. A., 2017. CRISPR–Cas9 Structures and Mechanisms. *Annual Review of Biophysics* **46**:505–529.)

sequence, then selected genome editing is possible. A more certain way to edit a DNA sequence is to use HDR to repair the DSB. Here, short DNA templates that have the desired sequence can be introduced to direct the repair process. Since these short templates, or donor DNAs, precisely replace the DNA around the DSB, the repaired DNA will have been edited to have the desired sequence, as determined by the sequence of the donor (Figure 12.24). That is, any DNA sequence can be edited using CRISPR-Cas9, just by expressing a gRNA having the same sequence and the proper PAM, then allowing endogenous systems to repair the DNA, as directed by donor DNA.

Thus, genomes can be edited by introducing vectors bearing the CRISPR-Cas9 system into target cells and expressing the vector so that its transcription produces the desired gRNA, and transcription plus translation yields Cas9 endonuclease. The cells will naturally repair the gRNA-targeted, Cas9-catalyzed DSB, as directed by a donor DNA, which is also provided. Because it is so easy and straightforward to make a gRNA of any desired sequence, CRISPR-Cas9 has revolutionized genome editing. CRISPR/Cas9 genome editing has been performed in dozens of species, including yeast, fruit flies, plants, fish, and mammals, including human cell lines.

If CRISPR edits are carried out in cells that ultimately could give rise to gametes (eggs and sperm) with edited genomes, the edited DNA and the trait it encodes will be inherited by future generations. Such experiments have been done in a wide variety of plants and animals, but ethical considerations discourage its application in human gametes. This ethical restraint was violated in 2018, when He Jiankui, an American-trained Chinese scientist introduced CRISPR-Cas9 into human eggs that had been fertilized with sperm from an HIV-positive father. The eggs were then implanted into the uterus of a woman who gave birth to two daughters. These fraternal twins were the first humans born with genomes edited by human germline gene therapy. Dr. He's objective was to use CRISPR-Cas9 to inactivate the CCR5 gene in the fertilized eggs that gave rise to these girls. CCR5 encodes a coreceptor for HIV (the virus that causes AIDS), and He's intention was to create children free of the risk of contracting AIDS. Worldwide condemnation was swift and He was imprisoned in China for his actions.

12.5e Base Editing with CRISPR-Cas9

Even though DSBs are repairable by NHEJ or HDR, it would be preferable in many cases if Cas9 could change the nucleotide sequence directly instead of cleaving the DNA. That is, could Cas9 be engineered to become a base editor rather than an endonuclease? This goal has been achieved. Inactivation of both (HNH and RuvC) endonuclease by mutations introduced into Cas9, coupled with the fusion of a base editor domain to the N-terminus of Cas9 creates a base-editing Cas9 (Figure 12.25). Various

Figure 12.25 CRISPR-Cas9 system engineering for base editing and prime editing. **(a)** Domain organization of the Cas9 protein. Cas9 protein consists of two prominent structural domains, the recognition (REC) lobe which is responsible for gRNA binding and the nuclease (NUC) lobe, the site of Cas9's two endonuclease activities—the HNH nuclease that cleaves the DNA strand that is complementary to the gRNA and the RuvC nuclease that cuts the noncomplementary DNA strand. The Rev lobe is also the location of the PAM-interacting (PI) domain of Cas9. The Rec and Nuc lobes are linked by the bridge helix (BH). Mutations can be introduced into Cas9 to inactivate its endonuclease functions or alter its PAM recognition specificity. **(b)** Engineering the Cas9 protein to create a base editor: Cas9 engineered to act as a base editor rather than an endonuclease. A cytidine deaminase (CBE) domain is fused to the N-terminus of Cas9 and its two endonuclease domains are inactivated by mutating them. These inactivated endonuclease functions are symbolized by superscript minus signs, as in HNH^- and RuvC^- . The N-terminal CBE fusion catalyzes base-editing of a specific C:G base pair to an T:A base pair, as selected by the appropriate gRNA. The gRNA is shown in green. Replacing the N-terminal cytidine deaminase fusion with a deoxyadenosine deaminase (ABE) fusion creates a Cas9 protein engineered to edit an A:T base by replacing it with a G:C base pair (not shown). **(c)** Engineering the Cas9 protein to create a prime editor. This Cas9 protein has been engineered to carry an N-terminal reverse transcriptase (RT) domain. The HNH endonuclease in this Cas9 version has been inactivated by mutation. The RuvC endonuclease remains functional, so that it can cut the nontemplate DNA strand to create a nick. Its guide RNA (green, shown bound to Cas9 and in greater detail below) is called a prime-editing guide RNA (pegRNA) to denote its new functions.

It consists of the target DNA-binding domain linked to an RT template region (RT template, blue) that encodes the editing changes desired in the gene, followed by a primer-binding sequence (PBS, orange). The PBS will base-pair with the nicked nontemplate strand of the target DNA and prime RT-catalyzed synthesis of new DNA. The nucleotide sequence in this new DNA is directed by the RT template of the pegRNA. (Adapted from Figures 3, 6, and 7 in Meaker, G. A., Hzir, E. J., and Gotochowski, T. E., 2020. Advances in engineering CRISPR-Cas9 as a molecular Swiss Army knife. *Synthetic Biology* 5:ysaa021.)

repurposed Cas9 proteins have been assembled in this way. Two examples are a Cas9 with an N-terminal cytosine deaminase base-editing (CBE) domain and a Cas9 with N-terminal deoxyadenosine deaminase (ABE) base-editing domain. The CBE domain converts a C in the targeted DNA sequence to a U, which then base-pairs with A. The result is base-editing of a C:G base pair in the target DNA to a T:A base pair. The ABE domain converts adenosine to inosine, which leads to a G:C base pair where an A:T base pair was.

12.5f Prime Editing with CRISPR-Cas9

A further innovation of CRISPR-Cas9 is to fuse a reverse transcriptase (RT) domain onto the N-terminus of Cas9 in which the HNH nuclease (but not the RuvC nuclease) has been inactivated. The gRNA is also redesigned by linking a desired RNA template (RT) sequence to the gRNA downstream from the PAM, followed by a primer binding site (PBS); this gRNA is termed a pegRNA (for primer editor guide RNA) (Figure 12.25). This CRISPR-Cas9 construct will nick the noncomplementary DNA strand via its RuvC endonuclease and then the engineered Cas9 will use its RT function to copy the RNA template region of the gRNA, as primed by the nicked region of the noncomplementary strand. In this manner, the nucleotide sequence of the target DNA can be rewritten as desired. Base-editing and prime-editing variants of CRISPR-Cas9 are being used to edit the genomes of plants and animals, including human cell lines.

12.5g Gene silencing with CRISPR-Cas9

Another addition to the CRISPR-Cas9 toolbox is CRISPRoff, which can be used to silence genes through DNA methylation (see the Human Biochemistry box in Chapter 11, DNA Methylation, CpG Islands, and Epigenetics). Catalytically inactive Cas9 (the HNH and RuvC endonuclease domains were inactivated by mutations) was fused with DNA-methyltransferase domains to create CRISPRoff. CRISPRoff is a programmable epigenetic memory writer that carries out gene silencing through DNA methylation and repressive histone modifications. It is paired with gRNAs selected from a gRNA library targeting 20,000 protein-encoding genes. Gene silencing using CRISPRoff has been shown to be durable, persisting for over 450 cell divisions and permanently silencing the genes it targets. Multiple genes can be turned off at the same time using a combination of gRNAs. CRISPRoff gene silencing could be reversed by a counterpart construct, CRISPRon, which erases the methylation modifications created by CRISPRoff through a Cas9-fused, DNA-demethylase domain and CRISPR inactivation of the host cell DNA methylation maintenance pathways. The beauty of this on/off CRISPR switch is that the nucleotide sequence of the genes is never altered. Instead, the genes are turned off and on at will through reversible DNA methylation.

12.6 | How Does High-Throughput Technology Allow Global Study of Millions of Genes or Molecules at Once?

A central scientific maxim is “To understand a system, you must perturb it.” By scrutinizing the consequences of perturbations, we gain some insight into how things work. Mutations and drugs are two obvious examples of this strategy. The beauty and challenge of biological systems—cells, organisms—is their extraordinary complexity. Traditional biochemical and molecular biological research has been limited by its inability to dissect and interpret more than one molecule at a time. The emergence of high-throughput technology (HTT) has dramatically altered the landscape; now researchers can look at millions of genes or molecules at once. Such studies are appropriately called global, as in global gene screening or global gene expression studies.

12.6a High-Throughput Screening

HTT relies on nanotechnological automation of experimental analysis, so that large numbers of molecules—DNA, RNA, proteins, or small molecules—can be screened for their functional role. Many of the relevant scientific questions today are based on screening genomes to reveal which genes are involved in a process, or screening total RNA to monitor those transcripts that are important, or finding which proteins among the thousands in a particular cell might be involved. The basic protocols of molecular biology described in this chapter underlie this technical revolution, but automation allows these protocols to be employed on a million-fold or more greater scale. The instrumentation used in HTT includes microtiter plates or chips bearing arrays of the molecules of interest (as shown in Figure 12.12), inkjet printers capable of delivering nanodrops of reagents, robotics for fluid handling and sample manipulation, software to manage the robotics, sensitive detectors that often rely on fluorescent markers to follow the progress of reactions, and computer interfaces for data processing and storage. The advent of HTT makes it easy to screen millions of DNA sequences (genes), transcripts, proteins, or small molecules in a single experiment. Such experiments are the realm of **high-throughput screening (HTS)**. An explosion of scientific discovery is being driven by HTS, and a dazzling number of applications of this technology is available. A review of these many applications is beyond the scope of this chapter, but the few examples which follow convey the scale of these new technologies.

12.6b High-Throughput RNAi Screening of Mammalian Genomes

In a pioneering study, shRNA-encoding DNA oligonucleotides 96 bases long were designed to correspond to all known genes in humans and in mice. A total of almost 200,000 oligonucleotides for each species was synthesized as a series of microarrays using inkjet DNA synthesis technology. These oligonucleotides could be recovered and cloned into DNA vectors capable of infecting mammalian cells. Introduction of these shRNA libraries into recipient mammalian cells (so that each cell receives a unique but different shRNA) leads to knockdown of the gene whose coding sequence is matched by the introduced shRNA. (“Knockdown of a gene” is a phrase describing a technique that prevents expression of a gene by targeting the mRNA product of that gene for destruction.) The challenge at this step is to design high-throughput screens to select for cells that have lost a particular function. Two examples would be: (1) Coexpress a GFP-labeled protein along with the shRNA to screen for cells deficient in protein degradation. Any cells with impaired capacity to degrade protein as a consequence of shRNA-mediated gene knockdown will display persistent fluorescence and can be easily selected. (2) Express the shRNA library in a mammalian cell line whose progression through mitosis can be monitored. shRNA knockdown of genes required for mitosis can be detected and identified.

12.6c High-Throughput Protein Screening

HTS screening of proteins allows efficient examination of a large number of protein variants or optimization of a wide range of experimental variables that might influence protein expression or purification. An example is the directed evolution of an enzyme, in this case, horseradish peroxidase. Directed evolution involves mutation of the enzyme-encoding gene and selection for variants displaying greater catalytic efficiency. Yeast cells were engineered to express horseradish peroxidase (HRP) from mutagenized libraries of HRP cDNA. A fluorogenic substrate allowed direct measurement of HRP enzymatic activity. A robotic microfluidic system created aqueous 6 pL droplets of yeast cells plus **fluorogenic substrate** that were 23 μm in diameter within an oil–water emulsion. (Fluorogenic substrates are molecules that, when acted on by an enzyme, yield a fluorescent product.) These droplets were passed through a drop sorter, which could sort 2000 drops per second over a 3 hour period. The drop sorter selected those droplets showing high fluorescence, discarding the rest. This HTS

selection scheme identified yeast cells expressing HRP variants that were more than twice as efficient as the wild type enzyme, with the best mutant being almost seven times more efficient. The amino acid sequence encoded by the cDNA in such a yeast cell provides insight regarding HRP structure and activity.

12.7 | What Is the Field of Synthetic Biology?

DNA is analogous to software. The information encoded in a genome is a program for the operation of an organism; indeed, it defines an organism. This realization has spawned the new science of **synthetic biology**. Synthetic biology (or SynBio) brings together genetics, cell biology, biochemistry, and molecular biology with the goal of redesigning organisms to have new abilities that serve useful purposes. DNA as code has opened the door to engineering new parts, devices, systems, and even organisms with features that before now have never existed in nature (Figure 12.26). Synthetic biology allows the rational design of new molecules at any level in the biological hierarchy: metabolites, protein, RNA, DNA. Engineering new systems with off-the-shelf, interchangeable parts easily introduced into well-studied cells, such as *E. coli*, yeast, or plants such as tobacco, presents exciting new possibilities for novel organisms to fit almost any imaginable purpose—environmental remediation, sustainability, biosensors, biofuel production, data storage, pharmaceutical synthesis and other therapeutic applications, and much more. Synthetic biology, with its reliance on mathematical modeling, engineering principles, and molecular biology, is a cross-discipline, integrated endeavor.

12.7a iGEM and BioBricks (Registry of Standard Biological Parts)

The International Genetically Engineered Machine (iGEM) competition is a excellent opportunity for students to gain hands-on experience in SynBio. iGEM is open to undergraduate students around the world (see <http://igem.org/About>). Originating in 2003, iGEM is dedicated to the advancement of synthetic biology through openness, education, and competition. The competition relies on kits of standardized and tested biological parts (**BioBricks**) available from the Registry of Standard Biological Parts (see <http://parts.igem.org/Help:Contents>). A basic part is defined as a DNA sequence that encodes for a specific biological function, such as a protein. An essential feature is that any part can be readily combined with any other part using standardized cloning procedures. A device is a composite of several parts, such as a ribosome-binding site, a protein-coding gene, and a terminator. A device has a cellular function, such as the promoter-driven expression of a protein-coding gene. At the beginning of each annual iGEM competition, kits of biological parts are given to competing collegiate teams. Teams can also design and build their own parts. The aim is to build a biological system and then express it in an appropriate chassis. A good example of an iGEM competition winner is shown under **Sustainability-Recycling Mixed Waste** below.

Mixed waste, a costly by-product of trash disposal, consists of non-recyclable plastics such as polyurethane as well as cellulose-based material (paper, wood) and other fibers. The 2013 iGEM team at Imperial College, London, designed synthetic biology systems to recover valuable components from mixed-waste trash for subsequent industrial use. *E. coli* cells were engineered to express and secrete polyurethane esterases that degrade polyurethane to form polyethylene glycol and poly(isothiocyanate), both of which can be recovered and sold back to the chemical industry. Further, engineered *E. coli* cells also received an operon encoding the three enzymes required for synthesis of poly- β -hydroxybutyrate (PHB) from acetyl-CoA, using the sugars released from cellulose breakdown as substrates for acetyl-CoA formation (Figure 12.27). PHB is a commercially valuable, environment-friendly polymer used in the manufacture of biodegradable plastic items, such as containers, eating utensils, food containers, and more.

The bottom-up organization of synthetic biology

Figure 12.26 The bottom-up organization of synthetic biology.

Figure 12.27 Synthetic biology applied to sustainability. Students on the 2013 iGEM competition team at Imperial College, London, designed new BioBricks so that they could engineer *E. coli* to process mixed waste and recover valuable commodities from trash. Two new BioBricks were created: one that expressed polyurethane esterases (PUR esterases) and another with a three-enzyme cassette for poly- β -hydroxybutyrate (PHB) synthesis. (Image courtesy of Imperial College, London).

12.7b Metabolic Engineering

Metabolic engineering is a subdiscipline of synthetic biology that aims to optimize production of a desired substance through genetic and regulatory manipulation of living cells. Metabolic engineering takes advantage of mathematical modeling, engineering principles, molecular biology, recombinant DNA technology, cell biology, and detailed biochemical knowledge about metabolic pathways. Cells are redesigned in ways that alter their fundamental metabolic capabilities in order to enhance biosynthesis of chemical compounds that have industrial, medical, or other important purposes. The synthesis of artemesinic acid provides an illustration of metabolic engineering.

Synthesis of Artemisinin, an Anti-Malaria Drug, in Yeast Artemisinin is part of the standard therapy for treatment of *Plasmodium falciparum* infection, the most dangerous form of malaria. More than 1 million people die each year from malaria. Artemisinin can be isolated from *Artemisia annua* (also known as sweet wormwood), a plant used in Chinese medicine for 2000 years. Chemical synthesis of artemisinin is difficult and costly, and sweet wormwood has limited availability and inconsistent quantities. These challenges prompted the Bill and Melinda Gates Foundation to give Professor Jay D. Keasling at the University of California, Berkeley, a \$43,000,000 grant to engineer artemisinin biosynthesis into yeast cells. The strategy he and his colleagues devised was to redirect farnesyl pyrophosphate (see Figure 9.23) production from sterol synthesis to **artemisinic acid** formation. Subsequently, artemisinic acid is used as a precursor for industrial-scale artemisinin synthesis (Figure 12.28). Keasling engineered yeast so that its genes encoding enzymes for farnesyl pyrophosphate (FPP) synthesis were up-regulated and one gene for conversion of FPP to sterols was down-regulated. Genes encoding enzymes for artemisinic acid from FPP were identified in *A. annua*, isolated, and cloned into *Saccharomyces cerevisiae* to create a metabolically engineered strain of yeast that produced more pharmacologically useful product than *A. annua* in less than one-tenth the time.

Figure 12.28 Structures of artemisinic acid and artemisinin. Yeast have been engineered to synthesize artemisinic acid, which can be recovered, chemically reduced, then photo-oxidized to yield artemisinin, a valuable anti-malarial drug. Artemisinin's pharmacological mechanism of action proceeds as follows: *Plasmodium falciparum* parasites infect red blood cells and use the hemoglobin they find there for food. The iron released from hemoglobin degradation activates the endoperoxide (-O-O-) group of artemisinin; in turn, activated artemisinin binds to and inactivates the plasmodium's calcium pump, causing death of the parasite.

Golden Rice—A Metabolic Engineering Success Story Vitamin A deficiency is a serious nutritional inadequacy in low-income countries, particularly in Africa and Southeast Asia. As many as 500,000 children suffer permanent blindness and half of these blinded children die within a year. Vitamin A-deficient children also suffer greater likelihood of death from common childhood infections, such as measles. Adequate intake of β -carotene, a precursor to vitamin A biosynthesis prevents development of deficiency (Figure 12.29).

The structure of β -carotene.

Figure 12.29 The structure of β -carotene.

Rice is the principal source of calories in the geographic regions where vitamin A deficiency is rampant. Genes encoding enzymes in the biosynthetic pathway for β -carotene that leads from isoprene (Figure 8.12) have been introduced into rice—a phytoene synthase from daffodils (or maize) and a phytoene desaturase from *Erwinia uredorova*, a common soil bacterium. These enzymes convert isoprene in the rice endosperm (the part that we eat) into lycopene (Figure 8.13) whose rings are then cyclized to give β -carotene. The β -carotene-rich rice grains turned a deep golden color, giving the rice its name. Further improvements led to a strain containing enough β -carotene that a single serving of this Golden Rice could deliver more than half the recommended daily intake for vitamin A.

Biochemistry of a Burger The Impossible Burger was created by Impossible Food, Inc., from a mixture of soy protein, potatoes, coconut fat, sunflower oil, and various binders such as corn starch to give it a proper meat texture. A patented process generates a meat flavor profile when a mixture of amino acids, sugars, and metabolites is heated with leghemoglobin. Leghemoglobin is a 143-residue protein produced by soybeans. Soybeans are legumes and leghemoglobin is named for its source. Leghemoglobin shows a striking structural similarity to both the α - and β -chains of mammalian hemoglobin (Figure 5.5) and the protein myoglobin of mammalian muscle. Like these proteins, leghemoglobin is intensely red in color, making it an ideal addition to a plant-derived burger substitute. The leghemoglobin gene was isolated from soybeans and cloned in yeast cells engineered to overexpress the synthesis of leghemoglobin. Yeast-synthesized plant leghemoglobin is a key ingredient in Impossible Burgers, now available at fast-food chains and grocery stores.

Chemoenzymatic Synthesis of Starch from CO_2 and H_2 Starch supplies the majority of calories in the diet of humans and livestock. Researchers have created a cell-free system for starch synthesis from carbon dioxide and hydrogen gas. The system is a 11-step hybrid pathway of enzymatically catalyzed and chemical reactions. The pathway begins with the chemical reduction of CO_2 by H_2 to form methanol, which is then enzymatically converted to formaldehyde. The next step, the union of three formaldehyde molecules to form dihydroxyacetone (DHA), was achieved by **formolase**, an enzyme created through a combination of computational protein design and directed evolution. DHA is a 3-carbon carbohydrate (Figure 7.3). Enzyme-catalyzed phosphorylation of DHA yielded a metabolic intermediate, dihydroxyacetone phosphate (DHAP), from which glucose-1-P and then starch could be synthesized by enzymes of carbohydrate metabolism common to plant cells. This chemoenzymatic system synthesized the conversion of CO_2 to starch over eight times faster than corn plants.

12.7c Synthetic Genomes

The creation of a fully synthetic genome was achieved in 2010 by J. Craig Venter's laboratory. These scientists assembled the complete 1.08-Mbp genome of *Mycoplasma mycoides* genome from 1078 DNA segments, each 1080 bp long, in a three-step process (Figure 12.30; see also the Critical Developments box Synthetic Life in Section 1.5). Each of these segments was constructed from chemically synthesized oligonucleotides. The assembly process was performed in yeast cells, and the completed *M. mycoides* genome was then introduced into *M. capricolum* recipient cells. Cells that could only grow if they contained a functional *M. mycoides* chromosome were obtained and analyzed for the presence of unique watermarks introduced during synthetic

Foundational Biochemistry Things You Should Know after Reading Chapter 12.

- The laboratory manipulation of nucleic acid molecules has led to the fields of recombinant DNA technology and genetic engineering.
- A clone in molecular biology refers to a population of molecules or cells identical to an original molecule or cell.
- Plasmids are very useful as vectors for cloning genes.
- Virtually any DNA sequence can be cloned.
- Chimeric plasmids can be constructed by inserting foreign DNA into a plasmid that has been cleaved by a restriction endonuclease.
- Directional cloning allows the insertion of foreign DNA into a plasmid or other vector in the desired orientation with respect to adjacent DNA elements such as promoters.
- Biologically functional chimeric plasmids have been used to transform cells, and the gene(s) they carry have been expressed in the recipient cells.
- Shuttle vectors are plasmids that can be propagated in two different organisms.
- Artificial chromosomes can be created from recombinant DNA.
- Genomic libraries are prepared from the total DNA in an organism.
- Genomic libraries can be screened for the presence of specific genes.
- PCR can be used to clone and amplify specific genes.
- Southern hybridization is a method for identifying specific DNA sequences in a large population of different DNA fragments.
- Probes for Southern hybridization can be prepared in a variety of ways.
- Northern hybridization is a technique for finding specific RNA sequences among a large population of RNA molecules.
- Western blotting is used to identify specific protein on an electrophoretic gel.
- RT-PCR (reverse transcriptase-PCR) is useful for cloning the gene that encodes a specific mRNA.
- cDNA libraries are libraries prepared from mRNA using reverse transcriptase.
- DNA microarrays, or gene chips, are arrays of different oligonucleotides immobilized on a chip.
- Expression vectors are designed so that the RNA transcripts or protein products encoded by specific genes can be expressed in host cells.
- RT-qPCR (real-time quantitative PCR) is used to determine levels of mRNA expression.
- cDNA libraries can be screened for the presence of specific protein-encoding cDNAs by using antibodies to the protein.
- Expression of proteins from cDNA libraries where the coding sequences of the cDNAs have been fused to easily isolated proteins or peptides allows rapid purification of the protein encoded by the cDNA.
- Reporter gene constructs are chimeric DNA molecules composed of gene regulatory sequences positioned next to an easily expressible gene product, such as GFP.
- Specific protein–protein interactions can be identified by the yeast two-hybrid system.
- Protein–protein interactions can also be revealed by immunoprecipitation using antibodies against one of the proteins.
- In vitro mutagenesis makes it possible to alter the nucleotide sequence of a cloned gene in a systematic way.
- RNAi (RNA interference) can be used to reveal the function of genes.
- Synthetic short-hairpin RNAs (shRNAs) target genes of choice.
- Human gene therapy can repair genetic deficiencies.
- Retroviruses and adenoviruses are useful vectors for human gene therapy.
- Successful human gene therapy has been achieved using the *ex vivo* approach with recombinant lentiviral vectors.
- Inherited genetic diseases successfully treated by human gene therapy include X-linked severe combined immunodeficiency (X-linked SCID), X-linked adrenoleukodystrophy (ALD), sickle-cell anemia, and β -thalassemia.
- A recombinant adenovirus was used to introduce a functional lipoprotein lipase gene *in vivo* in the first commercially approved human gene therapy.
- Genome engineering seeks to directly alter an organism's genome by changing its nucleotide sequence at one or more specific sites.
- DNA as code: DNA is analogous to software.
- CRISPR-Cas9 is a revolutionary new tool for genome engineering and gene editing.
- Base editing: CRISPR-Cas9 can be modified so that it acts as a base editor.
- Prime editing: CRISPR-Cas9 can be modified so that a fused reverse transcriptase domain will rewrite the genome.
- High-throughput technology (HTT) allows global study of millions of genes or molecules at the same time.
- shRNA-encoding DNA oligonucleotides corresponding to all known genes in humans and in mice can be used to knock down any gene.
- High-throughput protein screening using robotic microfluidic sample handling and a mutagenized peroxidase cDNA was used to demonstrate the directed evolution of an enzyme.
- Synthetic biology allows the rational design of new molecules at any level in the biological hierarchy.
- Examples of synthetic biology include the creation of biosensors, engineering organisms for recovery of industrial chemicals from waste, and metabolic engineering of organisms to produce pharmaceuticals or enhance their nutritional value.
- Synthetic genomes are chemically synthesized, fully functional genomes.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

- Method Terminology** For each item listed, indicate whether it functions in the process of DNA cloning, PCR, RNA interference, or CRISPR-Cas9: DNA polymerase, gRNA, primer, passenger strand, ligase, PAM, vector, dicer, endonuclease, siRNA, guide strand, linkers, and RISC.
- Protein, RNA, or DNA?** For each item listed, indicate whether it is composed of protein, RNA, or DNA: passenger strand, primer, Cas9, YAC, expressed sequence tags, gRNA, RISC, ligase, BAC, PAM, endonuclease, reverse transcriptase, HAC, vector, guide strand, linkers, DNA polymerase, dicer, and siRNA.
- Construction of a Recombinant Plasmid** A DNA fragment isolated from an *EcoRI* digest of genomic DNA was combined with a plasmid vector linearized by *EcoRI* digestion so that the sticky ends could anneal. Phage T4 DNA ligase was then added to the mixture. List all possible products of the ligation reaction.
- Overlapping Restriction Sites in a Plasmid Vector Polylinker** The nucleotide sequence of a polylinker in a particular plasmid vector is
 -GAATTCCTCGGGGATCCTCTAGAGTCGACCTGCAGGCATGC-
 This polylinker contains restriction sites for *Bam*HI, *Eco*RI, *Pst*I, *Sal*I, *Sma*I, *Sph*I, and *Xba*I. Indicate the location of each restriction site in this sequence. (See Table 10.2 for the cleavage sites of restriction enzymes.)
- Design a Vector Polylinker for Directional Cloning** A vector has a polylinker containing restriction sites in the following order: *Hind*III, *Sac*I, *Xho*I, *Bgl*II, *Xba*I, and *Cla*I.
 - Give a possible nucleotide sequence for the polylinker.
 - The vector is digested with *Hind*III and *Cla*I. A DNA segment contains a *Hind*III restriction site fragment 650 bases upstream from a *Cla*I site. This DNA fragment is digested with *Hind*III and *Cla*I, and the resulting *Hind*III–*Cla*I fragment is directionally cloned into the *Hind*III–*Cla*I-digested vector. Give the nucleotide sequence at each end of the vector and the insert and show that the insert can be cloned into the vector in only one orientation.
- The Number of Clones Needed to Screen a Yeast Genomic Library at 99% Confidence** Yeast (*S. cerevisiae*) has a genome size of 1.21×10^7 bp. If a genomic library of yeast DNA was constructed in a vector capable of carrying 16-kbp inserts, how many individual clones would have to be screened to have a 99% probability of finding a particular fragment?
- The Number of Clones Needed to Screen a Very Large Genomic Library at 99% Confidence** The South American lungfish has a genome size of 1.02×10^{11} bp. If a genomic library of lungfish DNA was constructed in a vector capable of carrying inserts averaging 45 kbp in size, how many individual clones would have to be screened to have a 99% probability of finding a particular DNA fragment?
- Calculating Number of Clones** The octopus' genome has been estimated to contain 2.7 billion bp. A library is generated using a vector capable of carrying 22 kbp inserts. How many individual clones would have to be screened to have a 99% probability of finding a particular DNA fragment?
- Designing Primers for PCR Amplification of a DNA Sequence** Given the following short DNA duplex of sequence (5'→3')
 ATGCCGTAGTCGATCATTACGATAGCATAGCACAGGGATCCA-
 CATGCACACATGACATAGGACAGATAGCAT
 what oligonucleotide primers (17-mers) would be required for PCR amplification of this duplex?
- Amplification of DNA Using PCR** A sample contains 10 copies of the DNA of interest. PCR is used to amplify the DNA of interest using excess amounts of primer. Three PCR kits are available with an average copying (doubling) efficiency of 75%, 85%, or 95%. Calculate and graph the number of DNA copies as a function of the number of PCR cycles, up to 20 cycles. (Assume that the number of copies would double with every cycle if the process were 100% efficient.)
- Designing a Primer** Consider the segment of DNA shown
 5'-AGATACCGCTGTGTATAACGGA-3'
 Design a primer that binds anywhere within this sequence with the following requirements: it is six nucleotides long and has a minimal number of C or G.
- A Polylinker for Expression of a β -Galactosidase Fusion Protein** Figure 12.3 shows a polylinker that falls within the β -galactosidase coding region of the *lacZ* gene. This polylinker serves as a cloning site in a fusion protein expression vector where the closed insert is expressed as a β -galactosidase fusion protein. Assume the vector polylinker was cleaved with *Bam*HI and then ligated with an insert whose sequence reads
 GATCCATTTATCCACCGAGAGCTGGTATCCCCAAAAGACG-
 GCC . . .
 What is the amino acid sequence of the fusion protein? Where is the junction between β -galactosidase and the sequence encoded by the insert? (Consult the genetic code table on the inside front cover to decipher the amino acid sequence.)
- Using PCR for the In Vitro Mutagenesis of a Protein Coding Sequence** The amino acid sequence across a region of interest in a protein is
 Asn-Ser-Gly-Met-His-Pro-Gly-Lys-Leu-Ala-Ser-Trp-Phe-Val-Gly-Asn-Ser
 The nucleotide sequence encoding this region begins and ends with an *Eco*RI site, making it easy to clone out the sequence and amplify it by PCR. Give the nucleotide sequence of this region. Suppose you wished to change the middle Ser residue to a Cys to study the effects of this change on the protein's activity. What is the sequence of the mutant oligonucleotide you would use for PCR amplification?
- Combinatorial Libraries: Calculating the Number of Sequence Possibilities for Oligonucleotides and Peptides** Combinatorial chemistry can be used to synthesize polymers such as oligopeptides or oligonucleotides. The number of sequence possibilities for a polymer is given by x^y , where x is the number of different monomer types (for example, 20 different amino acids in a protein or 4 different nucleotides in a nucleic acid) and y is the number of monomers in the oligomers.
 - Calculate the number of sequence possibilities for RNA oligomers 15 nucleotides long.
 - Calculate the number of amino acid sequence possibilities for pentapeptides.
- Combinatorial Libraries** Revisit Critical Developments in Biochemistry – Combinatorial Libraries. Consider the task of making oligonucleotides built from the four different nucleotides A, G, C and T.
 - Calculate the number of possible oligonucleotides that are 2 bp long.
 - Calculate the number of possible oligonucleotides that are 3 bp long.
 - Give a general formula for calculating the number of possible oligonucleotides of any length. Graph the number of possible oligonucleotides versus the length of the oligonucleotide.
- Using the Yeast Two-Hybrid System to Discover Protein–Protein Interactions** Imagine that you are interested in a protein that interacts with proteins of the cytoskeleton in human epithelial cells. Describe an experimental protocol based on the yeast two-hybrid system that would allow you to identify proteins that might interact with your protein of interest.

- 17. Studying Protein–Protein Interactions** Purified protein A was reported to bind purified protein B *in vitro* only in the presence of calcium ions. How would you confirm this finding *in vivo*? Use any figure from Chapter 12 to model your answer.
- 18. Preparing cDNA Libraries from Different Cells** Describe an experimental protocol for the preparation of two cDNA libraries, one from anaerobically grown yeast cells and the second from aerobically grown yeast cells.
- 19. Using Gene Chips to Study Differential Gene Expression** Describe an experimental protocol based on DNA microarrays (gene chips) that would allow you to compare gene expression in anaerobically grown yeast versus aerobically grown yeast.
- 20. Using Antibodies to Screen cDNA Libraries** You have an antibody against yeast hexokinase A (hexokinase is the first enzyme in the glycolytic pathway). Describe an experimental protocol using the cDNA libraries prepared in problem 18 that would allow you to identify and isolate the cDNA for hexokinase. Consulting Chapter 5 for protein analysis protocols, describe an experimental protocol to verify that the protein you have identified is hexokinase A.
- 21. Design of a Reporter Gene Construct to Study Promoter Function** In your experiment in problem 19, you discover a gene that is strongly expressed in anaerobically grown yeast but turned off in aerobically grown yeast. You name this gene *nox* (for no oxygen). You have the idea that you can engineer a yeast strain that senses O₂ levels if you can isolate the *nox* promoter. Describe how you might make a reporter gene construct using the *nox* promoter and how the yeast strain bearing this reporter gene construct might be an effective oxygen sensor.
- 22. CRISPR/Cas9: Design of a gRNA to Target the Human PVALB Gene** The human PVALB gene, which encodes the Ca²⁺-binding protein parvalbumin, can be targeted by CRISPR/Cas9, at the protospacer sequence -ATGCAGGAGGGTGGCGAGAGGGGCCGAGAT- followed by a -TGG-PAM trinucleotide. Give the sequence of the spacer region of a gRNA that will target the complementary DNA strand at this site. Include at the 3'-end of your gRNA sequence a region that will form a stem-loop structure with a 5'-AGCAUAGCUGUAAAAC- sequence downstream in the gRNA to create the dsRNA-binding site for Cas9.
- 23. Design of gRNA for CRISPR-Cas9** Consider the dsDNA shown, with the PAM sequence shown in bold and underlined. Design a 17-nucleotide-long segment of the guide RNA that would target this DNA segment.
- 5'-CTACGTACAATCGCATTGCGAGCTTCAGCAG
CTAGCATCA-3'
3'-GATGCATGTTAGCGTAACGTCGAAGTCGTCC
ATCGTAGT-5'
- 24. (Integrates with Chapter 10.)** In base editing with CRISPR-Cas9, specific enzymes are used to convert a C in DNA into a U, or an A into an I, through a deamination reaction.
- Revisiting the structures shown in Chapter 10, give the chemical reaction of the deamination of C into U.
 - Why is the C to U deamination not an instance of changing a DNA nucleotide into an RNA nucleotide?
 - Using the conversion of C into U as your model, give the chemical reactions for the deamination of A and G.

Biochemistry on the Web

- 25.** Search the National Center for Biotechnology Information (NCBI) website at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=Genome> to discover the number of organisms whose genome sequences have been completed. Explore the rich depository of sequence information available here by selecting one organism from the list and browsing through the contents available.
- 26.** Figure 12.1 shows restriction endonuclease sites for the plasmid pBR322. You want to clone a DNA fragment and select for it in transformed bacteria by using resistance to tetracycline and sensitivity to ampicillin as a way of identifying the recombinant plasmid. What restriction endonucleases might be useful for this purpose?
- 27.** Suppose in the amino acid sequence in Figure 12.8, tryptophan was replaced by cysteine. How would that affect the possible mRNA sequence? (Consult the inside front cover of this textbook for amino acid codons.) How many nucleotide changes are necessary in replacing Trp with Cys in this coding sequence? What is the total number of possible oligonucleotide sequences for the mRNA if Cys replaces Trp?

Think-Pair-Share Question

Gene Therapy A single-point mutation in its gene renders an enzyme hyperactive in the cytosol of cells. This phenomenon is observed when just one copy of the gene carries the mutation. Using the techniques discussed in this chapter (or other methods you may know of), propose therapeutic approaches to minimize the impact of or reverse this mutation. You can target the protein (enzyme), RNA, or DNA.

Enzymes—Kinetics and Specificity

13

Part II
Protein
Dynamics

Mark M. Lawrence/Corbis

There is more to life than increasing its speed.

Mahatma Gandhi (1869–1948)

- ◀ The Space Shuttle must accelerate from zero velocity to a velocity of more than 18,000 miles per hour in order to enter earth orbit. Its three main engines are powered by energy released in the reaction: $2\text{H}_2 + \text{O}_2 \rightarrow 2\text{H}_2\text{O}$. The rate of O_2 consumption per engine is 13,000 moles per second.

Essential Questions

At any moment, thousands of chemical reactions are taking place in any living cell. Enzymes are essential for these reactions to proceed at rates fast enough to sustain life.
What are enzymes, and what do they do?

Living organisms teem with metabolic activity. Thousands of chemical reactions are proceeding very rapidly at any given instant within all living cells. Virtually all of these transformations are mediated by **enzymes**—proteins (and occasionally RNA) specialized to catalyze metabolic reactions. The substances transformed in these reactions are often organic compounds that show little tendency for reaction outside the cell. An excellent example is glucose, a sugar that can be stored indefinitely on the shelf with no deterioration. Most cells quickly oxidize glucose, producing carbon dioxide and water, and releasing lots of energy:

(−2870 kJ/mol is the standard-state free energy change [ΔG°] for the oxidation of glucose.) In chemical terms, 2870 kJ is a large amount of energy, and glucose can be viewed as an energy-rich compound even though at ambient temperature it is not readily reactive with oxygen outside of cells. Stated another way, glucose represents **thermodynamic potentiality**: Its reaction with oxygen is strongly exergonic, but it doesn't occur under normal conditions. Enzymes can catalyze such thermodynamically favorable reactions, causing them to proceed at extraordinarily rapid rates. Enzymes accomplish this feat by lowering the energy of activation for the reaction (Figure 13.1). In glucose oxidation and countless other instances, enzymes provide cells with the ability to exert *kinetic control over thermodynamic potentiality*. That is, living systems use enzymes to accelerate and control the rates of vitally important biochemical reactions.

Key Questions

- 13.1 What Characteristic Features Define Enzymes?
- 13.2 How Can the Rate of an Enzyme-Catalyzed Reaction Be Defined in a Mathematical Way?
- 13.3 What Equations Define the Kinetics of Enzyme-Catalyzed Reactions?
- 13.4 What Can Be Learned from the Inhibition of Enzyme Activity?
- 13.5 What Is the Kinetic Behavior of Enzymes Catalyzing Bimolecular Reactions?
- 13.6 How Can Enzymes Be So Specific?
- 13.7 Are All Enzymes Proteins?
- 13.8 Is It Possible to Design an Enzyme to Catalyze Any Desired Reaction?

Figure 13.2 The breakdown of glucose by glycolysis provides a prime example of a metabolic pathway.

Figure 13.1 Reaction profile showing the large $\Delta G^\ddagger$ for glucose oxidation. Enzymes lower $\Delta G^\ddagger$, thereby accelerating rate.

Enzymes Are the Agents of Metabolic Function

Acting in sequence, enzymes form metabolic pathways by which nutrient molecules are degraded, energy is released and converted into metabolically useful forms, and precursors are generated and transformed to create the literally thousands of distinctive biomolecules found in any living cell (Figure 13.2). Situated at key junctions of metabolic pathways are specialized **regulatory enzymes** capable of sensing the momentary metabolic needs of the cell and adjusting their catalytic rates accordingly. The responses of these enzymes ensure the harmonious integration of the diverse and often divergent metabolic activities of cells so that the living state is promoted and preserved.

13.1 | What Characteristic Features Define Enzymes?

Enzymes are remarkably versatile biochemical catalysts that have three distinctive features in common: **catalytic power**, **specificity**, and **regulation**.

Chemistry in History

Dr. Maud Menten

Maud Leonora Menten (1879–1960) was one of the first women to receive an M.D. degree from the University of Toronto. In 1912, she moved to the laboratory of Leonor Michaelis in Berlin because women were not permitted to do research in Canada at that time. With Michaelis, she studied the kinetics of invertase, an enzyme that hydrolyzes sucrose to glucose and fructose. Michaelis and Menten found evidence for the formation of an enzyme-substrate complex, leading to their formulation of the Michaelis-Menten equation, which relates the rate of an enzyme-catalyzed reaction to the enzyme's affinity for its substrate.

To establish herself as an independent investigator, Menten got a Ph.D. in biochemistry from the University of Chicago in 1916 and joined the faculty at the University of Pittsburgh School of Medicine, where her research ranged from blood chemistry and enzymology to immunology. She was awarded a full professorship in 1949, the year she retired. She drove a Model T Ford around the University of Pittsburgh for 32 years, played the clarinet, spoke multiple languages, and went on an Arctic expedition.

13.1a Catalytic Power Is Defined as the Ratio of the Enzyme-Catalyzed Rate of a Reaction to the Uncatalyzed Rate

Enzymes display enormous catalytic power, accelerating reaction rates as much as 10^{26} over uncatalyzed levels, which is far greater than any synthetic catalysts can achieve. Enzymes accomplish these astounding feats in dilute aqueous solutions under mild conditions of temperature and pH. For example, the enzyme jack bean *urease* catalyzes the hydrolysis of urea:

At 20°C, the rate constant for the enzyme-catalyzed reaction is $3 \times 10^4/\text{s}$; the rate constant for the uncatalyzed hydrolysis of urea is $3 \times 10^{-10}/\text{s}$. Thus, 10^{14} is the ratio of the catalyzed rate to the uncatalyzed rate of reaction. Such a ratio is defined as the relative **catalytic power** of an enzyme, so the catalytic power of urease is 10^{14} .

13.1b Specificity Is the Term Used to Define the Selectivity of Enzymes for Their Substrates

Any given enzyme is very selective, both in the substances with which it interacts and in the reaction that it catalyzes. The substances upon which an enzyme acts are called **substrates**. In an enzyme-catalyzed reaction, none of the substrate is diverted into nonproductive side reactions, so no wasteful by-products are produced. It follows then that the products formed by a given enzyme are also very specific. This situation can be contrasted with your own experiences in the organic chemistry laboratory, where yields of 50% or even 30% are viewed as substantial accomplishments (Figure 13.3). The selective qualities of an enzyme are collectively recognized as its **specificity**. Intimate interaction between an enzyme and its substrates occurs through molecular recognition based on structural complementarity; such mutual recognition is the basis of specificity. The specific site on the enzyme where substrate binds and catalysis occurs is called the **active site**.

13.1c Regulation of Enzyme Activity Ensures That the Rate of Metabolic Reactions Is Appropriate to Cellular Requirements

Regulation of enzyme activity is essential to the integration and regulation of metabolism. Enzyme regulation is achieved in a variety of ways, ranging from controls over the amount of enzyme protein produced by the cell to more rapid, reversible interactions of the enzyme with metabolic inhibitors and activators. Chapter 15 is devoted to discussions of this topic. Because most enzymes are proteins, we can anticipate that the functional attributes of enzymes are due to the remarkable versatility found in protein structures.

13.1d Enzyme Nomenclature Provides a Systematic Way of Naming Metabolic Reactions

Traditionally, enzymes were named by adding the suffix *-ase* to the name of the substrate upon which they acted, as in *urease* for the urea-hydrolyzing enzyme or *phosphatase* for enzymes hydrolyzing phosphoryl groups from organic phosphate compounds. Other enzymes acquired names bearing little resemblance to their activity, such as the peroxide-decomposing enzyme *catalase* or the proteolytic enzymes (*proteases*) of the digestive tract, *trypsin* and *pepsin*. Because of the confusion that arose from these historical designations, an International Commission on

Figure 13.3 A 90% yield over 10 steps gives an overall yield of 35%. Yields in biological reactions must be substantially greater, otherwise, unwanted by-products would accumulate to unacceptable levels.

Enzymes was established to create a systematic basis for enzyme nomenclature. Although common names for many enzymes remain in use, all enzymes now are classified and formally named according to the reaction they catalyze. Six classes of reactions are recognized (Table 13.1). Within each class are subclasses, and under each subclass are sub-subclasses within which individual enzymes are listed. Classes, subclasses, sub-subclasses, and individual entries are each numbered so that a series of four numbers serves to specify a particular enzyme. A systematic name, descriptive of the reaction, is also assigned to each entry. To illustrate, consider the enzyme that catalyzes this reaction:

A phosphate group is transferred from ATP to the C-6-OH group of glucose, so the enzyme is a *transferase* (class 2, Table 13.1). Subclass 7 of transferases is *enzymes transferring phosphorus-containing groups*, and sub-subclass 1 includes those *phos-*

Table 13.1 Systematic Classification of Enzymes According to the Enzyme Commission			
E.C. Number	Systematic Name and Subclasses	E.C. Number	Systematic Name and Subclasses
1	Oxidoreductases (oxidation–reduction reactions)	4.1.2	Aldehyde lyases
1.1	Acting on CH—OH group of donors	4.2	C—O lyases
1.1.1	With NAD or NADP as acceptor	4.2.1	Hydrolases
1.1.3	With O ₂ as acceptor	4.3	C—N lyases
1.2	Acting on the >C=O group of donors	4.3.1	Ammonia lyases
1.2.3	With O ₂ as acceptor	5	Isomerases (isomerization reactions)
1.3	Acting on the CH—CH group of donors	5.1	Racemases and epimerases
1.3.1	With NAD or NADP as acceptor	5.1.3	Acting on carbohydrates
2	Transferases (transfer of functional groups)	5.2	Cis-trans isomerases
2.1	Transferring C-1 groups	6	Ligases (formation of bonds with ATP cleavage)
2.1.1	Methyltransferases	6.1	Forming C—O bonds
2.1.2	Hydroxymethyltransferases and formyltransferases	6.1.1	Amino acid–RNA ligases
2.1.3	Carboxyltransferases and carbamoyltransferases	6.2	Forming C—S bonds
2.2	Transferring aldehydic or ketonic residues	6.3	Forming C—N bonds
2.3	Acytransferases	6.4	Forming C—C bonds
2.4	Glycosyltransferases	6.4.1	Carboxylases
2.6	Transferring N-containing groups	7	Translocases (the movement of a molecule or ion across a membrane)
2.6.1	Aminotransferases	7.1	Translocation of protons
2.7	Transferring P-containing groups	7.1.1	Linked to oxidoreductases
2.7.1	With an alcohol group as acceptor	7.2	Translocation of inorganic cations
3	Hydrolases (hydrolysis reactions)	7.2.1	Linked to the hydrolysis of a nucleoside triphosphate
3.1	Cleaving ester linkage	7.3	Translocation of inorganic anions and their chelates
3.1.1	Carboxylic ester hydrolases	7.3.1	Linked to the hydrolysis of a nucleoside triphosphate
3.1.3	Phosphoric monoester hydrolases	7.4	Translocation of amino acids and peptides
3.1.4	Phosphoric diester hydrolases	7.4.1	Linked to the hydrolysis of a nucleoside triphosphate
4	Lyases (bond cleavage by means other than hydrolysis or oxidation)	7.5	Translocation of carbohydrates and their derivatives
4.1	C—C lyases	7.5.1	Linked to the hydrolysis of a nucleoside triphosphate
4.1.1	Carboxy-lyases	7.6	Translocation of other compounds

For details, see <https://enzyme.expasy.org>.

phosphotransferases with an alcohol group as an acceptor. Entry 2 in this sub-subclass is ATP:D-glucose-6-phosphotransferase, and its classification number is 2.7.1.2. In use, this number is preceded by the letters E.C., denoting the Enzyme Commission. For example, entry 1 in the same sub-subclass is E.C.2.7.1.1, ATP:D-hexose-6-phosphotransferase, an ATP-dependent enzyme that transfers a phosphate to the 6-OH of hexoses (that is, it is nonspecific regarding its hexose acceptor). These designations can be cumbersome, so in everyday usage, traditional names are commonly used. The glucose-specific enzyme E.C.2.7.1.2 is called *glucokinase*, and the nonspecific E.C.2.7.1.1 is known as *hexokinase*. *Kinase* is a term for enzymes that are ATP-dependent phosphotransferases.

13.1e Coenzymes and Cofactors Are Nonprotein Components Essential to Enzyme Activity

Many enzymes carry out their catalytic function relying solely on their protein structure. Many others require nonprotein components, called **cofactors** (Table 13.2). Cofactors may be metal ions or organic molecules referred to as **coenzymes**. Coenzymes and cofactors provide proteins with chemically versatile functions not found in amino acid side chains. Many coenzymes are vitamins or contain vitamins as part of their structure. Usually coenzymes are actively involved in the catalytic reaction of the enzyme, often serving as intermediate carriers of functional groups in the conversion of substrates to products. In most cases, a coenzyme is firmly associated with its enzyme, perhaps even by covalent bonds, and it is difficult to separate the two. Such tightly bound coenzymes are referred to as **prosthetic groups** of the enzyme. The catalytically active complex of protein and prosthetic group is called the **holoenzyme**. The protein without the prosthetic group is called the **apoenzyme**; it is catalytically inactive.

Table 13.2 Enzyme Cofactors: A Few Examples of Metal Ions and Coenzymes and the Enzymes with Which They Are Associated

Metal Ions and Some Enzymes That Require Them		Coenzymes Serving as Transient Carriers of Specific Atoms or Functional Groups		
Metal Ion	Enzyme	Coenzyme	Entity Transferred	Representative Enzyme
Fe ²⁺ or Fe ³⁺	Cytochrome oxidase	Thiamine pyrophosphate (TPP)	Aldehydes	Pyruvate dehydrogenase
	Catalase	Flavin adenine dinucleotide (FAD)	Hydrogen atoms	Succinate dehydrogenase
	Peroxidase	Nicotinamide adenine dinucleotide (NAD)	Hydride ion (:H ⁻)	Alcohol dehydrogenase
Cu ²⁺	Cytochrome oxidase			
Zn ²⁺	DNA polymerase	Coenzyme A (CoA)	Acyl groups	Acetyl-CoA carboxylase
	Carbonic anhydrase	Pyridoxal phosphate (PLP)	Amino groups	Aspartate aminotransferase
	Alcohol dehydrogenase			
Mg ²⁺	Hexokinase	5'-Deoxyadenosylcobalamin (vitamin B ₁₂)	H atoms and alkyl groups	Methylmalonyl-CoA mutase
	Glucose-6-phosphatase			
Mn ²⁺	Arginase	Biotin (biocytin)	CO ₂	Propionyl-CoA carboxylase
K ⁺	Pyruvate kinase (also requires Mg ²⁺)	Tetrahydrofolate (THF)	Other one-carbon groups, such as formyl and methyl groups	Thymidylate synthase
Ni ²⁺	Urease			
Mo	Nitrate reductase			
Se	Glutathione peroxidase			

13.2 How Can the Rate of an Enzyme-Catalyzed Reaction Be Defined in a Mathematical Way?

Kinetics is the branch of science concerned with the rates of reactions. The study of **enzyme kinetics** addresses the biological roles of enzymatic catalysts and how they accomplish their remarkable feats. Enzyme kineticists seek to determine the maximum reaction velocity that the enzyme can attain and its binding affinities for substrates and inhibitors. Coupled with studies on the structure and chemistry of the enzyme, analysis of the enzymatic rate under different reaction conditions yields insights regarding the enzyme's mechanism of catalytic action. Such information is essential to an overall understanding of metabolism.

Significantly, this information can be exploited to control and manipulate the course of metabolic events. The science of pharmacology relies on such a strategy. **Pharmaceuticals**, or **drugs**, are often special inhibitors specifically targeted at a particular enzyme in order to overcome infection or to alleviate illness. A detailed knowledge of the enzyme's kinetics is indispensable to rational drug design and successful pharmacological intervention.

13.2a Chemical Kinetics Provides a Foundation for Exploring Enzyme Kinetics

Before beginning a discussion of enzyme kinetics, it will be fruitful to review some basic principles of chemical kinetics. **Chemical kinetics** is the study of the rates of chemical reactions. Consider a reaction of overall stoichiometry:

Although we treat this reaction as a simple, one-step conversion of A to P, it more likely occurs through a sequence of elementary reactions, each of which is a simple molecular process, as in

where I and J represent intermediates in the reaction. Precise description of all of the elementary reactions in a process is necessary to define the overall reaction mechanism for $A \longrightarrow P$.

Let us assume that $A \longrightarrow P$ is an elementary reaction and that it is spontaneous and essentially irreversible. Irreversibility is easily assumed if the rate of P conversion to A is very slow or the concentration of P (expressed as [P]) is negligible under the conditions chosen. The **velocity**, v , or **rate**, of the reaction $A \longrightarrow P$ is the amount of P formed or the amount of A consumed per unit time, t . That is,

$$v = \frac{d[P]}{dt} \quad \text{or} \quad v = -\frac{d[A]}{dt} \quad (13.1)$$

The mathematical relationship between reaction rate and concentration of reactant(s) is the **rate law**. For this simple case, the rate law is

$$v = \frac{-d[A]}{dt} = k[A] \quad (13.2)$$

From this expression, it is obvious that the rate is proportional to the concentration of A, and k is the proportionality constant, or **rate constant**. The units of k are $(\text{time})^{-1}$, usually s^{-1} . v is a function of [A] to the first power, or in the terminology of kinetics, v is first-order with respect to A. For an elementary reaction, the **order** for any reactant is given by its exponent in the rate equation. The number of molecules that must simultaneously interact is defined as the **molecularity** of the reaction. Thus, the simple elementary reaction of $A \longrightarrow P$ is a **first-order reaction**. Figure 13.4 portrays the course of a first-order reaction as a function of time. The rate of decay of a radioactive isotope, like ^{14}C or ^{32}P , is a first-order reaction, as is an intramolecular rearrangement, such as $A \longrightarrow P$. Both are **unimolecular reactions** (the molecularity equals 1).

Figure 13.4 Plot of the course of a first-order reaction. The half-time, $t_{1/2}$, is the time for one-half of the starting amount of A to disappear.

13.2b Bimolecular Reactions Are Reactions Involving Two Reactant Molecules

Consider the more complex reaction, where two molecules must react to yield products:

Assuming this reaction is an elementary reaction, its molecularity is 2; that is, it is a **bimolecular reaction**. The velocity of this reaction can be determined from the rate of disappearance of either A or B, or the rate of appearance of P or Q:

$$v = \frac{-d[A]}{dt} = \frac{-d[B]}{dt} = \frac{d[P]}{dt} = \frac{d[Q]}{dt} \quad (13.3)$$

The rate law is

$$v = k[A][B] \quad (13.4)$$

Since A and B must collide in order to react, the rate of their reaction will be proportional to the concentrations of both A and B. Because it is proportional to the product of two concentration terms, the reaction is **second-order** overall, first-order with respect to A and first-order with respect to B. Were the elementary reaction $2A \longrightarrow P + Q$, the rate law would be $v = k[A]^2$, second-order overall and second-order with respect to A. Second-order rate constants have the units of (concentration) $^{-1}(\text{time})^{-1}$, as in $M^{-1} s^{-1}$.

Molecularities greater than 2 are rarely found and those greater than 3, never. The likelihood of simultaneous collision of three molecules is very, very small. When the overall stoichiometry of a reaction is greater than two (for example, as in $A + B + C \longrightarrow$ or $2A + B \longrightarrow$), the reaction almost always proceeds via unimolecular or bimolecular elementary steps, and the overall rate obeys a simple first- or second-order rate law.

At this point, it may be useful to remind ourselves of an important caveat that is the first principle of kinetics: *Kinetics cannot prove a hypothetical mechanism*. Kinetic experiments can only rule out various alternative hypotheses because they do not fit the data. However, through thoughtful kinetic studies, a process of elimination of alternative hypotheses leads ever closer to the reality.

13.2c Catalysts Lower the Free Energy of Activation for a Reaction

In a first-order chemical reaction, the conversion of A to P occurs because, at any given instant, a fraction of the A molecules has the energy necessary to achieve a reactive condition known as the **transition state**. In this state, the probability is very high that the particular rearrangement accompanying the $A \longrightarrow P$ transition will occur. This transition state sits at the apex of the energy profile in the energy diagram

Figure 13.5 Energy diagram for a chemical reaction ($A \rightarrow P$) and the effects of (a) raising the temperature from T_1 to T_2 or (b) adding a catalyst.

describing the energetic relationship between A and P (Figure 13.5). The average free energy of A molecules defines the initial state, and the average free energy of P molecules is the final state along the reaction coordinate. The rate of any chemical reaction is proportional to the concentration of reactant molecules (A in this case) having this transition-state energy. The higher this energy is above the average energy, the smaller the fraction of molecules that will have this energy and the slower the reaction will proceed. The height of this energy barrier is called the **free energy of activation**, $\Delta G^\ddagger$. Specifically, $\Delta G^\ddagger$ is the energy required to raise the average energy of 1 mol of reactant (at a given temperature) to the transition-state energy. The relationship between activation energy and the rate constant of the reaction, k , is given by the **Arrhenius equation**:

$$k = Ae^{-\Delta G^\ddagger/RT} \quad (13.5)$$

where A is a constant for a particular reaction (not to be confused with the reactant species, A, that we're discussing). Another way of writing this is $1/k = (1/A)e^{\Delta G^\ddagger/RT}$. That is, k is inversely proportional to $e^{\Delta G^\ddagger/RT}$. Therefore, if the energy of activation decreases, the reaction rate increases.

13.2d Decreasing $\Delta G^\ddagger$ Increases Reaction Rate

We are familiar with two general ways that rates of chemical reactions may be accelerated. First, the temperature can be raised. This will increase the kinetic energy of reactant molecules, and more reactant molecules will possess the energy to reach the transition state (Figure 13.5a). In effect, increasing the average energy of reactant molecules makes the energy difference between the average energy and the transition-state energy smaller. (Also note that the equation $k = Ae^{-\Delta G^\ddagger/RT}$ demonstrates that k increases as T increases.) The rates of many chemical reactions are doubled by a 10°C rise in temperature. Second, the rates of chemical reactions can also be accelerated by catalysts. Catalysts work by lowering the energy of activation rather than by raising the average energy of the reactants (Figure 13.5b). Catalysts accomplish this remarkable feat by combining transiently with the reactants in a way that promotes their entry into the reactive, transition-state condition. Two aspects of catalysts are worth noting: (1) They are regenerated after each reaction cycle ($A \rightarrow P$),

and therefore can be used over and over again; and (2) catalysts have *no* effect on the overall free energy change in the reaction, the free energy difference between A and P (Figure 13.5b).

13.3 What Equations Define the Kinetics of Enzyme-Catalyzed Reactions?

Examination of the change in reaction velocity as the reactant concentration is varied is one of the primary measurements in kinetic analysis. Returning to $A \rightarrow P$, a plot of the reaction rate as a function of the concentration of A yields a straight line whose slope is k (Figure 13.6). The more A that is available, the greater the rate of the reaction, v . Similar analyses of enzyme-catalyzed reactions involving only a single substrate yield remarkably different results (Figure 13.7). At low concentrations of the substrate S, v is proportional to $[S]$, as expected for a first-order reaction. However, v does not increase proportionally as $[S]$ increases, but instead begins to level off. At high $[S]$, v becomes virtually independent of $[S]$ and approaches a maximal limit. The value of v at this limit is written $V_{\max}$. Because rate is no longer dependent on $[S]$ at these high concentrations, the enzyme-catalyzed reaction is now obeying **zero-order kinetics**; that is, the rate is independent of the reactant (substrate) concentration. This behavior is a **saturation effect**: When v shows no increase even though $[S]$ is increased, the system is saturated with substrate. Such plots are called **substrate saturation curves**. The physical interpretation is that every enzyme molecule in the reaction mixture has its substrate-binding site occupied by S. Indeed, such curves were the initial clue that an enzyme interacts directly with its substrate by binding it.

Figure 13.6 A plot of v versus $[A]$ for the unimolecular chemical reaction, $A \rightarrow P$, yields a straight line having a slope equal to k .

13.3a The Substrate Binds at the Active Site of an Enzyme

An enzyme molecule is often (but not always) orders of magnitude larger than its substrate. In any case, its active site, the place on the enzyme where S binds, comprises only a portion of the overall enzyme structure. The conformation of the active site is structured to form a special pocket or cleft whose three-dimensional architecture is complementary to the structure of the substrate. The enzyme and the substrate molecules recognize each other through this structural complementarity. The substrate binds to the enzyme through relatively weak forces—H bonds, ionic bonds (salt bridges), and van der Waals interactions between sterically complementary clusters of atoms.

Figure 13.7 Substrate saturation curve for an enzyme-catalyzed reaction. The amount of enzyme is constant, and the velocity of the reaction is determined at various substrate concentrations. The reaction rate, v , as a function of $[S]$ is described mathematically by a rectangular hyperbola. The H_2O molecule provides a rough guide to scale.

13.3b The Michaelis–Menten Equation Is the Fundamental Equation of Enzyme Kinetics

Leonor Michaelis and Maud L. Menten proposed a general theory of enzyme action in 1913 consistent with observed enzyme kinetics. Their theory was based on the assumption that the enzyme, E, and its substrate, S, associate reversibly to form an enzyme–substrate complex, ES:

This association/dissociation is assumed to be a rapid equilibrium, and K_s is the *enzyme–substrate dissociation constant*. At equilibrium,

$$k_{-1}[ES] = k_1[E][S] \quad (13.7)$$

and

$$K_s = \frac{[E][S]}{[ES]} = \frac{k_{-1}}{k_1} \quad (13.8)$$

Product, P, is formed in a second step when ES breaks down to yield E + P.

E is then free to interact with another molecule of S.

13.3c Rate Calculations Assume That [ES] Remains Constant During an Enzymatic Reaction

The interpretations of Michaelis and Menten were refined and extended in 1925 by Briggs and Haldane, who assumed the concentration of the enzyme–substrate complex ES quickly reaches a constant value in such a dynamic system. That is, ES is formed as rapidly from E + S as it disappears by its two possible fates: dissociation to regenerate E + S and reaction to form E + P. This assumption is termed the **steady-state assumption** and is expressed as

$$\frac{d[ES]}{dt} = 0 \quad (13.10)$$

That is, the change in concentration of ES with time, t , is 0. Figure 13.8 illustrates the time course for formation of the ES complex and establishment of the steady-state condition.

13.3d A Calculations Are Simplified If Velocity Measurements Are Made Immediately after Adding S

One other simplification will be advantageous. Because enzymes accelerate the rate of the reverse reaction as well as the forward reaction, it would be helpful to ignore any reverse reaction by which E + P might form ES. The velocity of this back reaction would be given by $v = k_{-2}[E][P]$. However, if we observe only the *initial velocity* for the reaction immediately after E and S are mixed in the absence of P, the rate of any back reaction is negligible because its rate will be proportional to [P], and [P] is essentially 0. Given such simplification, we now analyze the system described by Equation 13.9 in order to describe the initial velocity v as a function of [S] and amount of enzyme.

The total amount of enzyme is fixed and is given by the formula

$$\text{Total enzyme, } [E_T] = [E] + [ES] \quad (13.11)$$

Figure 13.8 Time course for a typical enzyme-catalyzed reaction obeying the Michaelis–Menten, Briggs–Haldane models for enzyme kinetics. The early stage of the time course is shown in greater magnification in the bottom graph.

where $[E]$ is free enzyme and $[ES]$ is the amount of enzyme in the enzyme–substrate complex. From Equation 13.9, the rate of $[ES]$ formation is

$$v_f = k_1([E_T] - [ES])[S]$$

where

$$[E_T] - [ES] = [E] \quad (13.12)$$

From Equation 13.9, the rate of $[ES]$ disappearance is

$$v_d = k_{-1}[ES] + k_2[ES] = (k_{-1} + k_2)[ES] \quad (13.13)$$

At steady state, $d[ES]/dt = 0$, and therefore, $v_f = v_d$. So,

$$k_1([E_T] - [ES])[S] = (k_{-1} + k_2)[ES] \quad (13.14)$$

Rearranging gives

$$\frac{([E_T] - [ES])[S]}{[ES]} = \frac{(k_{-1} + k_2)}{k_1} \quad (13.15)$$

13.3e The Michaelis Constant, K_m , Is Defined as $(k_{-1} + k_2)/k_1$

The ratio of constants $(k_{-1} + k_2)/k_1$ is itself a constant and is defined as the **Michaelis constant**, K_m

$$K_m = \frac{(k_{-1} + k_2)}{k_1} \quad (13.16)$$

Note from Equation 13.15 that K_m is given by the ratio of two concentrations ($[E_T] - [ES]$ and $[S]$) to one ($[ES]$), so K_m has the units of *molarity*. (Also, because the units of k_{-1} and k_2 are in time^{-1} and the units of k_1 are $M^{-1}\text{time}^{-1}$, the units of K_m are M .) From Equation 13.15, we can write

$$\frac{([E_T] - [ES])[S]}{[ES]} = K_m \quad (13.17)$$

which rearranges to

$$[ES] = \frac{[E_T][S]}{K_m + [S]} \quad (13.18)$$

Now, the most important parameter in the kinetics of any reaction is the **rate of product formation**. This rate is given by

$$v = \frac{d[P]}{dt} \quad (13.19)$$

and for this reaction

$$v = k_2[ES] \quad (13.20)$$

Substituting the expression for $[ES]$ from Equation 13.18 into Equation 13.20 gives

$$v = \frac{k_2[E_T][S]}{K_m + [S]} \quad (13.21)$$

The product $k_2[E_T]$ has special meaning. When $[S]$ is high enough to saturate all of the enzyme, the velocity of the reaction, v , is maximal. At saturation, the amount of $[ES]$ complex is equal to the total enzyme concentration, E_T , its maximum possible value. From Equation 13.20, the initial velocity v then equals $k_2[E_T] = V_{\max}$. Written symbolically, when $[S] \gg [E_T]$ (and K_m), $[E_T] = [ES]$ and $v = V_{\max}$. Therefore,

$$V_{\max} = k_2[E_T] \quad (13.22)$$

Substituting this relationship into the expression for v gives the **Michaelis–Menten equation**:

$$v = \frac{V_{\max}[S]}{K_m + [S]} \quad (13.23)$$

This equation says that the initial rate of an enzyme-catalyzed reaction, v , is determined by two constants, K_m and $V_{\max}$, and the initial concentration of substrate.

13.3f When $[S] = K_m$, $v = V_{\max}/2$

We can provide an operational definition for the constant K_m by rearranging Equation 13.23 to give

$$K_m = [S] \left(\frac{V_{\max}}{v} - 1 \right) \quad (13.24)$$

Then, at $v = V_{\max}/2$, $K_m = [S]$. That is, K_m is defined by the substrate concentration that gives a velocity equal to one-half the maximal velocity. Table 13.3 gives the K_m values of some enzymes for their substrates.

13.3g Plots of v versus $[S]$ Illustrate the Relationships between $V_{\max}$, K_m , and Reaction Order

The Michaelis–Menten equation (Equation 13.23) describes a curve known from analytical geometry as a *rectangular hyperbola*. In such curves, as $[S]$ is increased, v approaches the limiting value, $V_{\max}$, in an asymptotic fashion. $V_{\max}$ can be approximated experimentally from a substrate saturation curve (Figure 13.7), and K_m can be derived from $V_{\max}/2$, so the two constants of the Michaelis–Menten equation can be obtained from plots of v versus $[S]$. Note, however, that actual estimation of $V_{\max}$, and consequently K_m , is only approximate from such graphs. That is, according to Equation 13.23, to get $v = 0.99 V_{\max}$, $[S]$ must equal $99 K_m$, a concentration that may be difficult to achieve in practice.

From Equation 13.23, when $[S] \gg K_m$, then $v = V_{\max}$. That is, v is no longer dependent on $[S]$, so the reaction is obeying zero-order kinetics. Also, when $[S] < K_m$, then $v \approx (V_{\max}/K_m)[S]$. That is, the rate, v , approximately follows a first-order rate equation, $v = k'[S]$, where $k' = V_{\max}/K_m$.

K_m and $V_{\max}$, once known explicitly, define the rate of the enzyme-catalyzed reaction, provided that:

1. The reaction involves only one substrate, *or* if the reaction is multisubstrate, the concentration of only one substrate is varied and the concentrations of all other substrates are held constant.

Table 13.3 K_m Values for Some Enzymes

Enzyme	Substrate	K_m (mM)
Carbonic anhydrase	CO ₂	12
Hexokinase	Glucose	0.15
	Fructose	1.5
β -Galactosidase	Lactose	4
Aspartate aminotransferase	Aspartate	0.9
	α -Ketoglutarate	0.1
	Oxaloacetate	0.04
	Glutamate	4
Threonine deaminase	Threonine	5
Pyruvate carboxylase	HCO ₃ [−]	1.0
	Pyruvate	0.4
	ATP	0.06
Lysozyme	Hexa- <i>N</i> -acetylglucosamine	0.006

- The reaction $ES \rightarrow E + P$ is irreversible, *or* the experiment is limited to observing only initial velocities where $[P] = 0$.
- $[S]_0 > [E_T]$ and $[E_T]$ is held constant.
- All other variables that might influence the rate of the reaction (temperature, pH, ionic strength, and so on) are held constant.

13.3h Turnover Number Defines the Activity of One Enzyme Molecule

The **turnover number** of an enzyme, k_{cat} , is a measure of its maximal catalytic activity. k_{cat} is defined as the number of substrate molecules converted into product per enzyme molecule per unit time when the enzyme is saturated with substrate. The turnover number is also referred to as the **molecular activity** of the enzyme. For the simple Michaelis–Menten reaction (Equation 13.9) under conditions of initial velocity measurements, $k_2 = k_{\text{cat}}$. Provided the concentration of enzyme, $[E_T]$, in the reaction mixture is known, k_{cat} can be determined from V_{max} . At saturating $[S]$, $v = V_{\text{max}} = k_2 [E_T]$. Thus,

$$k_2 = \frac{V_{\text{max}}}{[E_T]} = k_{\text{cat}} \quad (13.25)$$

The term k_{cat} represents the kinetic efficiency of the enzyme. Table 13.4 lists turnover numbers for some representative enzymes. Catalase has the highest turnover number known; each molecule of this enzyme can degrade 40 million molecules of H_2O_2 in 1 second! At the other end of the scale, lysozyme requires 2 seconds to cleave a glycosidic bond in its glycan substrate.

In many situations, the actual molar amount of the enzyme is not known. However, its amount can be expressed in terms of the activity observed. The International Commission on Enzymes defines **one international unit** as *the amount that catalyzes the formation of 1 micromole of product in 1 minute*. (Because enzymes are very sensitive to factors such as pH, temperature, and ionic strength, the conditions of assay must be specified.) In the process of purifying enzymes from cellular sources, many extraneous proteins may be present. Then, the units of enzyme activity are expressed as enzyme units per mg protein, a term known as **specific activity** (see Table 5.1).

13.3i The Ratio, k_{cat}/K_m , Defines the Catalytic Efficiency of an Enzyme

Under physiological conditions, $[S]$ is seldom saturating and k_{cat} itself is not particularly informative. That is, the in vivo ratio of $[S]/K_m$ usually falls in the range of 0.01 to 1.0, so active sites often are not filled with substrate. Nevertheless, we can derive a meaningful index of the efficiency of Michaelis–Menten–type enzymes under these conditions by using the following equations. As presented in Equation 13.23, if

$$v = \frac{V_{\text{max}}[S]}{K_m + [S]}$$

and $V_{\text{max}} = k_{\text{cat}} [E_T]$, then

$$v = \frac{k_{\text{cat}}[E_T][S]}{K_m + [S]} \quad (13.26)$$

When $[S] \ll K_m$, the concentration of free enzyme, $[E]$, is approximately equal to $[E_T]$, so

$$v = \left(\frac{k_{\text{cat}}}{K_m} \right) [E][S] \quad (13.27)$$

That is, k_{cat}/K_m is an apparent second-order rate constant for the reaction of E and S to form product. Because K_m is inversely proportional to the affinity of the enzyme for its substrate and k_{cat} is directly proportional to the kinetic efficiency of the enzyme, k_{cat}/K_m provides an index of the catalytic efficiency of an enzyme operating at substrate concentrations substantially below saturation amounts.

Table 13.4 Values of k_{cat} (Turnover Number) for Some Enzymes

Enzyme	k_{cat} (s^{-1})
Catalase	40,000,000
Carbonic anhydrase	1,000,000
Acetylcholinesterase	14,000
Penicillinase	2000
Lactate dehydrogenase	1000
Chymotrypsin	100
DNA polymerase I	15
Lysozyme	0.5

An interesting point emerges for the cases where $k_{\text{cat}} = k_2$. Then

$$\frac{k_{\text{cat}}}{K_m} = \frac{k_1 k_2}{k_{-1} + k_2} \quad (13.28)$$

But k_1 must always be greater than or equal to $k_1 k_2 / (k_{-1} + k_2)$. That is, the reaction can go no faster than the rate at which E and S come together. Thus, k_1 sets the upper limit for k_{cat}/K_m . In other words, *the catalytic efficiency of an enzyme cannot exceed the diffusion-controlled rate of combination of E and S to form ES*. In H_2O , the rate constant for such diffusion is approximately $10^9/\text{M} \cdot \text{s}$ for small substrates (for example, glyceraldehyde 3-P) and an order of magnitude smaller ($\approx 10^8/\text{M} \cdot \text{s}$) for substrates the size of nucleotides. Those enzymes that are most efficient in their catalysis have k_{cat}/K_m ratios approaching this value. Their catalytic velocity is limited only by the rate at which they encounter S; enzymes this efficient have achieved the so-called catalytic perfection. All E and S encounters lead to reaction because such catalytically perfect enzymes can channel S to the active site, regardless of where S hits E. Table 13.5 lists the kinetic parameters of several enzymes in this category. Note that k_{cat} and K_m both show a substantial range of variation in this table, even though their ratio falls around $10^8/\text{M} \cdot \text{s}$.

13.3j Linear Plots Can Be Derived from the Michaelis–Menten Equation

Because of the hyperbolic shape of v versus $[\text{S}]$ plots, V_{max} can be determined only from an extrapolation of the asymptotic approach of v to some limiting value as $[\text{S}]$ increases indefinitely (Figure 13.7); and K_m is derived from that value of $[\text{S}]$, giving $v = V_{\text{max}}/2$. However, several rearrangements of the Michaelis–Menten equation transform it into a straight-line equation. The best known of these is the **Lineweaver–Burk double-reciprocal plot**. Taking the reciprocal of both sides of the Michaelis–Menten equation, Equation 13.23, yields the equality

$$\frac{1}{v} = \left(\frac{K_m}{V_{\text{max}}} \right) \left(\frac{1}{[\text{S}]} \right) + \frac{1}{V_{\text{max}}} \quad (13.29)$$

This conforms to $y = mx + b$ (the equation for a straight line), where $y = 1/v$; m , the slope, is K_m/V_{max} ; $x = 1/[\text{S}]$; and $b = 1/V_{\text{max}}$. Plotting $1/v$ versus $1/[\text{S}]$ gives a straight line whose x -intercept is $-1/K_m$, whose y -intercept is $1/V_{\text{max}}$, and whose slope is K_m/V_{max} (Figure 13.9).

Table 13.5 Enzymes Whose k_{cat}/K_m Approaches the Diffusion-Controlled Rate of Association with Substrate

Enzyme	Substrate	k_{cat} (s^{-1})	K_m (M)	k_{cat}/K_m ($\text{M}^{-1} \text{s}^{-1}$)
Acetylcholinesterase	Acetylcholine	1.4×10^4	9×10^{-5}	1.6×10^8
Carbonic anhydrase	CO_2	1×10^6	0.012	8.3×10^7
	HCO_3^-	4×10^5	0.026	1.5×10^7
Catalase	H_2O_2	4×10^7	1.1	4×10^7
Crotonase	Crotonyl-CoA	5.7×10^3	2×10^{-5}	2.8×10^8
Fumarase	Fumarate	800	5×10^{-6}	1.6×10^8
	Malate	900	2.5×10^{-5}	3.6×10^7
Triosephosphate isomerase	Glyceraldehyde-3-phosphate*	4.3×10^3	1.8×10^{-5}	2.4×10^8
β -Lactamase	Benzylpenicillin	2×10^3	2×10^{-5}	1×10^8

* K_m for glyceraldehyde-3-phosphate is calculated on the basis that only 3.8% of the substrate in solution is unhydrated and therefore reactive with the enzyme.

Adapted from Fersht, A., *Enzyme Structure and Mechanism*, 2nd ed. New York: W. H. Freeman, 1985.

$$\frac{1}{v} = \frac{K_m}{V_{\max}} \left(\frac{1}{[S]} \right) + \frac{1}{V_{\max}}$$

Figure 13.9 The Lineweaver–Burk double-reciprocal plot.

The **Hanes–Woolf plot** is another rearrangement of the Michaelis–Menten equation that yields a straight line:

Multiplying both sides of Equation 13.29 by $[S]$ gives

$$\frac{[S]}{v} = [S] \left(\frac{K_m}{V_{\max}} \right) \left(\frac{1}{[S]} \right) + \frac{[S]}{V_{\max}} = \frac{K_m}{V_{\max}} + \frac{[S]}{V_{\max}} \quad (13.30)$$

and

$$\frac{[S]}{v} = \left(\frac{1}{V_{\max}} \right) [S] + \frac{K_m}{V_{\max}} \quad (13.31)$$

Graphing $[S]/v$ versus $[S]$ yields a straight line where the slope is $1/V_{\max}$, the y -intercept is $K_m/V_{\max}$, and the x -intercept is $-K_m$, as shown in Figure 13.10. The Hanes–Woolf plot has the advantage of not overemphasizing the data obtained at low $[S]$, a fault inherent in the Lineweaver–Burk plot. The common advantage of these plots is that they allow both K_m and $V_{\max}$ to be accurately estimated by extrapolation of straight lines rather than asymptotes. Computer fitting of v versus $[S]$ data to the Michaelis–Menten equation is more commonly done than graphical plotting.

$$\frac{[S]}{v} = \left(\frac{1}{V_{\max}} \right) [S] + \frac{K_m}{V_{\max}}$$

Figure 13.10 A Hanes–Woolf plot of $[S]/v$ versus $[S]$.

A Deeper Look

An Example of the Effect of Amino Acid Substitutions on K_m and k_{cat} : Wild-Type and Mutant Forms of Human Sulfite Oxidase

Mammalian sulfite oxidase is the last enzyme in the pathway for degradation of sulfur-containing amino acids. Sulfite oxidase (SO) catalyzes the oxidation of sulfite (SO_3^{2-}) to sulfate (SO_4^{2-}), using the heme-containing protein, cytochrome *c*, as electron acceptor:

Isolated sulfite oxidase deficiency is a rare and often fatal genetic disorder in humans. The disease is characterized by severe neurological abnormalities, revealed as convulsions shortly after birth. R. M. Garrett and K. V. Rajagopalan at Duke University Medical Center have isolated the human cDNA for sulfite oxidase from the cells of normal (*wild-type*) and SO-deficient individuals. The expression of these SO cDNAs in transformed *Escherichia coli* cells allowed the isolation and kinetic analysis of wild-type and mutant forms of SO, including one (designated R160Q) in which the Arg at position 160 in the polypeptide chain is replaced by Gln. A genetically engineered version of SO (designated R160K) in which Lys replaces Arg¹⁶⁰ was also studied.

Kinetic Constants for Wild-Type and Mutant Sulfite Oxidase

Enzyme	K_m^{sulfite} (μM)	k_{cat} (s^{-1})	k_{cat}/K_m ($10^6 \text{ M}^{-1} \text{ s}^{-1}$)
Wild-type	17	18	1.1
R160Q	1900	3	0.0016
R160K	360	5.5	0.015

Replacing R¹⁶⁰ in sulfite oxidase by Q increases K_m , decreases k_{cat} , and markedly diminishes the catalytic efficiency (k_{cat}/K_m) of the enzyme. The R160K mutant enzyme has properties intermediate between wild-type and the R160Q mutant form. The substrate, SO_3^{2-} , is strongly anionic, and R¹⁶⁰ is one of several Arg residues situated within the SO substrate-binding site. Positively charged side chains in the substrate-binding site facilitate SO_3^{2-} binding and catalysis, with Arg being optimal in this role.

13.3k Nonlinear Lineweaver–Burk or Hanes–Woolf Plots Are a Property of Regulatory Enzymes

If the kinetics of the reaction disobey the Michaelis–Menten equation, the violation is revealed by a departure from linearity in these straight-line graphs. We shall see in Chapter 15 that such deviations from linearity are characteristic of the kinetics of regulatory enzymes known as **allosteric enzymes**. Such regulatory enzymes are very important in the overall control of metabolic pathways.

13.3l Enzymatic Activity Is Strongly Influenced by pH

Enzyme–substrate recognition and the catalytic events that ensue are greatly dependent on pH. An enzyme possesses an array of ionizable side chains and prosthetic groups that not only determine its secondary and tertiary structure, but may also be intimately involved in its active site. Furthermore, the substrate itself often has ionizing groups, and one or another of the ionic forms may preferentially interact with the enzyme. Enzymes in general are active only over a limited pH range, and most have a particular pH at which their catalytic activity is optimal. These effects of pH may be due to effects on K_m or V_{max} or both. Figure 13.11 illustrates the relative activity of four enzymes as a function of pH. Trypsin, an intestinal protease, has a slightly alkaline pH optimum, whereas pepsin, a gastric protease, acts in the acidic confines of the stomach and has a pH optimum near 2. Papain, a protease found in papaya, is relatively insensitive to pHs between 4 and 8. Cholinesterase activity is pH sensitive below pH 7 but not between pH 7 and 10. The cholinesterase activity–pH profile suggests that an ionizable group with a pK_a near six is essential to its activity. Might this group be a histidine side chain within its active site? Although the pH optimum of an enzyme often reflects the pH of its normal environment, the optimum may not be precisely the same. This difference suggests that the pH–activity response of an enzyme may be a factor in the intracellular regulation of its activity.

13.3m The Response of Enzymatic Activity to Temperature Is Complex

Like most chemical reactions, the rates of enzyme-catalyzed reactions generally increase with increasing temperature. However, at temperatures above 50°C to 60°C, enzymes typically show a decline in activity (Figure 13.12). Several effects are operating

Optimum pH of some enzymes	
Enzyme	Optimum pH
Pepsin	1.5
Catalase	7.6
Trypsin	7.7
Fumarase	7.8
Ribonuclease	7.8
Arginase	9.7

Figure 13.11 The pH activity profiles of four different enzymes.

here: (1) the characteristic increase in reaction rate with temperature; (2) a temperature-dependent equilibrium between active enzyme (E_{active}) and the catalytically inactive but not denatured state of the enzyme (E_{inact}); and (3) thermal denaturation of protein structures at higher temperatures. An equilibrium model of these effects proposed by Roy M. Daniel and Michael J. Danson fits well with experimentally observed responses of enzyme activity versus temperature,

where X designates the irreversibly inactivated form of the enzyme and k_{inact} is the first-order rate constant for thermal denaturation. Most enzymatic reactions double in rate for every 10°C rise in temperature (that is, $Q_{10} = 2$, where Q_{10} is defined as *the ratio of activities at two temperatures 10 degrees Celsius apart*) as long as the enzyme is stable and fully active. Some enzymes, such as those catalyzing reactions having very high activation energies, show proportionally greater Q_{10} values. The increasing rate with increasing temperature is ultimately offset by the temperature-dependent equilibrium between active and inactive states of the native enzyme, and, ultimately, the denaturation of protein structure at elevated temperatures. The fit of this model with the experimental data supports the existence of E_{inact} . Indeed, E_{inact} reflects the intrinsic flexibility, and, hence, greater thermal sensitivity of the active site, compared with the rest of the enzyme's structure. Not all enzymes are quite so thermally labile. For example, the enzymes of thermophilic prokaryotes (*thermophilic* = heat-loving) found in geothermal springs retain full activity at temperatures in excess of 85°C.

Figure 13.12 The effect of temperature on enzyme activity.

13.4 What Can Be Learned from the Inhibition of Enzyme Activity?

Systematic perturbations are a basic tool of experimental scientists; much can be learned about the normal workings of any system by inducing changes in it and then observing the effects of the change. If the velocity of an enzymatic reaction is decreased or **inhibited** by some agent, the kinetics of the reaction obviously have been perturbed. The study of enzyme inhibition has contributed significantly to our understanding of enzymes.

13.4a Enzymes May Be Inhibited Reversibly or Irreversibly

Enzyme inhibitors are classified in several ways. The inhibitor may interact either reversibly or irreversibly with the enzyme. **Reversible inhibitors** interact with the enzyme through noncovalent association/dissociation reactions. In contrast, **irreversible inhibitors** usually form covalent bonds with side chains or prosthetic groups in the

enzyme. That is, the consequence of irreversible inhibition is a decrease in the concentration of active enzyme. The kinetics observed are consistent with this interpretation, as will be discussed later in this chapter.

13.4b Reversible Inhibitors May Bind at the Active Site or at Some Other Site

Reversible inhibitors fall into three major categories: competitive, noncompetitive, and uncompetitive. **Competitive inhibitors** are characterized by the fact that the substrate and inhibitor compete for the same binding site on the enzyme, the so-called active site or **substrate-binding site**. Thus, increasing the concentration of S favors the likelihood of S binding to the enzyme instead of the inhibitor, I. That is, high [S] can overcome the effects of I. The effects of the other major types, noncompetitive and uncompetitive inhibition, cannot be overcome by increasing [S]. The three types can be distinguished by the particular patterns obtained when the kinetic data are analyzed in linear plots, such as double-reciprocal (Lineweaver–Burk) plots. A general formulation for common inhibitor interactions in our simple enzyme kinetic model would include

Competitive Inhibition Consider the following system:

where an inhibitor, I, binds *reversibly* to the enzyme at the same site as S. S-binding and I-binding are mutually exclusive, *competitive* processes. Formation of the ternary complex, IES, where both S and I are bound, is physically impossible. This condition leads us to anticipate that S and I must share a high degree of structural similarity because they bind at the same site on the enzyme. Also notice that, in this model, EI does not react to give rise to E + P. That is, I is not changed by interaction with E. The rate of the product-forming reaction is $v = k_2[ES]$.

It is revealing to compare the equation for the uninhibited case, Equation 13.23 (the Michaelis–Menten equation) with Equation 13.43 for the rate of the enzymatic reaction in the presence of a fixed concentration of the competitive inhibitor, [I]

$$v = \frac{V_{\max}[S]}{K_m + [S]} \tag{13.35}$$

$$v = \frac{V_{\max}[S]}{[S] + K_m \left(1 + \frac{[I]}{K_I} \right)} \tag{13.36}$$

(see also Table 13.6). The K_m term in the denominator in the inhibited case is increased by the factor $(1 + [I]/K_I)$; thus, v is less in the presence of the inhibitor, as expected. In the absence of I, the two equations are identical. Figure 13.13 shows a Lineweaver–Burk

Table 13.6 The Effect of Various Types of Inhibitors on the Michaelis–Menten Rate Equation and on Apparent K_m and Apparent $V_{\max}$			
Inhibition Type	Rate Equation	Apparent K_m	Apparent $V_{\max}$
None	$v = V_{\max}[S]/(K_m + [S])$	K_m	$V_{\max}$
Competitive	$v = V_{\max}[S]/([S] + K_m(1 + [I]/K_I))$	$K_m(1 + [I]/K_I)$	$V_{\max}$
Noncompetitive	$v = (V_{\max}[S]/(1 + [I]/K_I))/(K_m + [S])$	K_m	$V_{\max}/(1 + [I]/K_I)$
Mixed	$v = V_{\max}[S]/((1 + [I]/K_I)K_m + (1 + [I]/K_I')[S])$	$K_m(1 + [I]/K_I)/(1 + [I]/K_I')$	$V_{\max}/(1 + [I]/K_I')$
Uncompetitive	$v = V_{\max}[S]/(K_m + [S](1 + [I]/K_I'))$	$K_m/(1 + [I]/K_I')$	$V_{\max}/(1 + [I]/K_I')$

K_I is defined as the enzyme-inhibitor dissociation constant $K_I = [E][I]/[EI]$; K_I' is defined as the enzyme–substrate complex/inhibitor dissociation constant $K_I' = [ES][I]/[IES]$.

Figure 13.13 Lineweaver–Burk plot of competitive inhibition, showing lines for no I, [I], and 2[I]. Note that when [S] is infinitely large ($1/[S] \approx 0$), $V_{\max}$ is the same, whether I is present or not. **(right)** Enzyme (grey) modeled with three binding sites: oval, substrate-binding site; triangle, uncompetitive inhibitor-binding site; and rectangle, noncompetitive inhibitor-binding site. Substrate, yellow; competitive inhibitor, orange. Note that S and competitive inhibitor compete for binding at the substrate-binding site.

plot of competitive inhibition. Several features of competitive inhibition are evident. First, at a given [I], v decreases ($1/v$ increases). When [S] becomes infinite, $v = V_{\max}$ and is unaffected by I because all of the enzyme is in the ES form. Note that the value of the $-x$ -intercept decreases as [I] increases. This $-x$ -intercept is often termed the *apparent* K_m (or K_{mapp}) because it is the K_m apparent under these conditions. The diagnostic criterion for competitive inhibition is that $V_{\max}$ is unaffected by I; that is, all lines share a common y -intercept. This criterion is also the best experimental indication of binding at the same site by two substances. Competitive inhibitors resemble S structurally.

A Deeper Look

The Equations of Competitive Inhibition

Given the relationships between E, S, and I described previously and recalling the steady-state assumption that $d[\text{ES}]/dt = 0$, from Equations (13.14) and (13.16) we can write

$$\text{ES} = \frac{k_1[\text{E}][\text{S}]}{(k_2 + k_{-1})} = \frac{[\text{E}][\text{S}]}{K_m} \quad (13.37)$$

Assuming that $\text{E} + \text{I} \rightleftharpoons \text{EI}$ reaches rapid equilibrium, the rate of EI formation, $v_f' = k_3[\text{E}][\text{I}]$, and the rate of disappearance of EI, $v_d' = k_{-3}[\text{EI}]$, are equal. So,

$$k_3[\text{E}][\text{I}] = k_{-3}[\text{EI}] \quad (13.38)$$

Therefore,

$$[\text{EI}] = \frac{k_3}{k_{-3}} [\text{E}][\text{I}] \quad (13.39)$$

If we define K_1 as k_{-3}/k_3 , an enzyme-inhibitor dissociation constant, then

$$[\text{EI}] = \frac{[\text{E}][\text{I}]}{K_1} \quad (13.40) \quad \text{or}$$

knowing $[\text{E}_T] = [\text{E}] + [\text{ES}] + [\text{EI}]$. Then

$$[\text{E}_T] = [\text{E}] + \frac{[\text{E}][\text{S}]}{K_m} + \frac{[\text{E}][\text{I}]}{K_1} \quad (13.41)$$

Solving for [E] gives

$$[\text{E}] = \frac{K_1 K_m [\text{E}_T]}{(K_1 K_m + K_1 [\text{S}] + K_m [\text{I}])} \quad (13.42)$$

Because the rate of product formation is given by $v = k_2[\text{ES}]$, from Equation 13.34 we have

$$v = \frac{k_2 [\text{E}][\text{S}]}{K_m} \quad (13.43)$$

So,

$$v = \frac{(k_2 K_1 [\text{E}_T][\text{S}])}{(K_1 K_m + K_1 [\text{S}] + K_m [\text{I}])} \quad (13.44)$$

Because $V_{\max} = k_2[\text{E}_T]$,

$$v = \frac{V_{\max} [\text{S}]}{K_m + [\text{S}] + \frac{K_m [\text{I}]}{K_1}} \quad (13.45)$$

$$v = \frac{V_{\max} [\text{S}]}{[\text{S}] + K_m \left(1 + \frac{[\text{I}]}{K_1}\right)} \quad (13.46)$$

Figure 13.14 Structures of succinate, the substrate of succinate dehydrogenase (SDH), and malonate, the competitive inhibitor. Fumarate (the product of SDH action on succinate) is also shown.

Succinate Dehydrogenase—A Classic Example of Competitive Inhibition The citric acid cycle enzyme *succinate dehydrogenase* (SDH) is competitively inhibited by malonate. Figure 13.14 shows the structures of succinate and malonate. The structural similarity between them is obvious and is the basis of malonate's ability to mimic succinate and bind at the active site of SDH. However, unlike succinate, which is oxidized by SDH to form fumarate, malonate cannot lose two hydrogens; consequently, it is unreactive.

Noncompetitive Inhibition Noncompetitive inhibitors interact with both E and ES (or with S and ES, but this is a rare and specialized case). In this case, the inhibitor is not binding to the same site as S, and the inhibition cannot be overcome by raising [S]. There are two types of noncompetitive inhibition: pure and mixed.

Pure Noncompetitive Inhibition In this situation, the binding of I by E has no effect on the binding of S by E. That is, S and I bind at different sites on E, and binding of I does not affect binding of S. Consider the system

Pure noncompetitive inhibition occurs if $K_I = K_I'$. This situation is relatively uncommon; the Lineweaver–Burk plot for such an instance is given in Figure 13.15. Note that K_m is unchanged by I (the x -intercept remains the same, with or without I). Note also that the apparent $V_{\max}$ decreases. A similar pattern is seen if the amount of enzyme in the experiment is decreased. Thus, it is as if I lowered [E].

Mixed Noncompetitive Inhibition In this situation, the binding of I by E influences the binding of S by E. Either the binding sites for I and S are near one another or conformational changes in E caused by I affect S binding. In this case, K_I and K_I' , as defined previously, are not equal. Both the apparent K_m and the apparent $V_{\max}$ are altered by the presence of I, and $K_m/V_{\max}$ is not constant (Figure 13.16). This inhibitory pattern is commonly encountered. A reasonable explanation is that the inhibitor is binding at a site distinct from the active site yet is influencing the binding of S at the active site. Presumably, these effects are transmitted via alterations in the protein's conformation. Table 13.6 includes the rate equations and apparent K_m and $V_{\max}$ values for both types of noncompetitive inhibition.

Uncompetitive Inhibition Completing the set of inhibitory possibilities is uncompetitive inhibition. Unlike competitive inhibition (where I combines only with E) or noncompetitive inhibition (where I combines with E and ES), in uncompetitive inhibition, I combines only with ES.

Figure 13.15 Lineweaver–Burk plot of pure noncompetitive inhibition. (a) Enzyme (grey) modeled with three binding sites: oval, substrate-binding site; triangle, uncompetitive-inhibitor binding site; and rectangle, noncompetitive-inhibitor binding site. (b) $1/v$ versus $1/[S]$ plot for pure noncompetitive inhibition. Substrate, yellow; noncompetitive inhibitor, orange. Note that I does not alter K_m but that it decreases $V_{\max}$.

Figure 13.16 Lineweaver–Burk plot of mixed noncompetitive inhibition. Note that both intercepts and the slope change in the presence of I. (a) When K_I is less than K'_I ; (b) when K_I is greater than K'_I .

Because IES does not lead to product formation, the observed rate constant for product formation, k_2 , is uniquely affected. In simple Michaelis–Menten kinetics, k_2 is the only rate constant that is part of both $V_{\max}$ and K_m . The pattern obtained in Lineweaver–Burk plots is a set of parallel lines (Figure 13.17). A clinically important example is the action of lithium in alleviating manic depression; Li^+ ions are uncompetitive inhibitors of *myo*-inositol monophosphatase. Some pesticides are also uncompetitive inhibitors, such as Roundup, an uncompetitive inhibitor of 3-enolpyruvylshikimate-5-P synthase, an enzyme essential to aromatic amino acid biosynthesis.

13.4c Enzymes Also Can Be Inhibited in an Irreversible Manner

If the inhibitor combines irreversibly with the enzyme—for example, by covalent attachment—the kinetic pattern seen is like that of noncompetitive inhibition because the net effect is a loss of active enzyme. Usually, this type of inhibition can be distinguished from the noncompetitive, reversible inhibition case because the reaction of I with E (and/or ES) is not instantaneous. Instead, there is a *time-dependent decrease in*

Figure 13.17 Lineweaver–Burk plot of uncompetitive inhibition. (a) Enzyme (grey) modeled with three binding sites: oval, substrate-binding site; triangle, uncompetitive inhibitor binding site; and rectangle, noncompetitive inhibitor binding site. Substrate = yellow; uncompetitive inhibitor = orange. (b) $1/v$ versus $1/[S]$ plot for uncompetitive inhibition. Note that both intercepts change but the slope (K_m/V_{max}) remains constant in the presence of I.

enzymatic activity as $E + I \rightarrow EI$ proceeds, and the rate of this inactivation can be followed. Also, unlike reversible inhibitions, dilution or dialysis of the enzyme-inhibitor solution does not shift the equilibrium between $E + I$ and dissociate the EI complex. Since dilution does not restore enzyme activity, the inhibitor must be irreversibly bound.

Suicide Substrates—Mechanism-Based Enzyme Inactivators Suicide substrates are synthetic inhibitory substrate analogs designed so that, via normal catalytic action of the enzyme, a very reactive group is generated. This reactive group then forms a covalent bond with a nearby functional group within the active site of the enzyme, thereby causing irreversible inhibition. Suicide substrates, also called *Trojan horse substrates*, are a type of **affinity label**. As substrate analogs, they bind with specificity and high affinity to the enzyme active site; in their reactive form, they become covalently bound to the enzyme. This covalent link effectively labels a particular functional group within the active site, identifying the group as a key player in the enzyme's catalytic cycle.

Penicillin—A Suicide Substrate Several drugs in current medical use are mechanism-based enzyme inactivators. For example, the antibiotic **penicillin** exerts its effects by covalently reacting with an essential serine residue in the active site of *glycopeptide transpeptidase*, an enzyme that acts to crosslink the peptidoglycan chains during synthesis of bacterial cell walls (Figure 13.18). Penicillin consists of a thiazolidine ring fused to a β -lactam ring to which a variable R group is attached. A reactive peptide bond in the β -lactam ring covalently attaches to a serine residue in the active site of the glycopeptide transpeptidase. (The conformation of penicillin around its reactive peptide bond resembles the transition state of the normal glycopeptide transpeptidase substrate.) The penicilloyl–enzyme complex is catalytically inactive. Once cell wall synthesis is blocked, the bacterial cells are very susceptible to rupture by osmotic lysis and bacterial growth is halted.

Figure 13.18 Penicillin is an irreversible inhibitor of the enzyme glycopeptide transpeptidase, also known as glycoprotein peptidase, which catalyzes an essential step in bacterial cell wall synthesis.

13.5 What Is the Kinetic Behavior of Enzymes Catalyzing Bimolecular Reactions?

Thus far, we have considered only the simple case of enzymes that act upon a single substrate, S. This situation is not common. Usually, enzymes catalyze reactions in which two (or even more) substrates take part.

Consider the case of an enzyme catalyzing a reaction involving two substrates, A and B, and yielding the products P and Q:

Enzymatic reactions involving two substrates are called **bisubstrate reactions**. In general, bisubstrate reactions proceed by one of two possible routes:

- Both A and B are bound to the enzyme and then the reaction occurs to give P + Q:

Reactions of this type are defined as **sequential** or **single-displacement reactions**. They can be either of two distinct classes:

- random**, where either A or B may bind to the enzyme first, followed by the other substrate, or
- ordered**, where A, designated the *leading substrate*, must bind to E first before B can be bound.

Both classes of single-displacement reactions are characterized by lines that intersect to the left of the $1/v$ axis in Lineweaver–Burk plots where the rates observed with different fixed concentrations of one substrate (B) are graphed versus a series of concentrations of A (Figure 13.19).

Figure 13.19 Single-displacement bisubstrate mechanism.

Human Biochemistry

Viagra—An Unexpected Outcome in a Program of Drug Design

Prior to the accumulation of detailed biochemical information on metabolism, enzymes, and receptors, drugs were fortuitous discoveries made by observant scientists; the discovery of penicillin as a bacteria-killing substance by Fleming is an example. Today, **drug design** is the rational application of scientific knowledge and principles to the development of pharmacologically active agents. A particular target for therapeutic intervention is identified (such as an enzyme or receptor involved in illness), and chemical analogs of its substrate or ligand are synthesized in hopes of finding an inhibitor (or activator) that will serve as a drug to treat the illness. Sometimes the outcome is unanticipated, as the story of **Viagra** (sildenafil citrate) reveals.

When the smooth muscle cells of blood vessels relax, blood flow increases and blood pressure drops. Such relaxation is the result of decreases in intracellular $[Ca^{2+}]$ triggered by increases in intracellular $[cGMP]$ (which in turn is triggered by nitric oxide, NO; see Chapter 32). Cyclic GMP (cGMP) is hydrolyzed by *phosphodiesterases* to form 5'-GMP, and the muscles contract again. Scientists at Pfizer rea-

soned that, if phosphodiesterase inhibitors could be found, they might be useful drugs to treat *angina* (chest pain due to inadequate blood flow to heart muscle) or *hypertension* (high blood pressure). The phosphodiesterase (PDE) prevalent in vascular muscle is PDE 5, one of at least eleven different subtypes of PDE in human cells. The search was on for substances that inhibit PDE 5, but not the other prominent PDE types, and Viagra was found. Disappointingly, Viagra showed no significant benefits for angina or hypertension, but some men in clinical trials reported penile erection. Apparently, Viagra led to an increase in $[cGMP]$ in penile vascular tissue, allowing vascular muscle relaxation, improved blood flow, and erection. A drug was born.

In a more focused way, detailed structural data on enzymes, receptors, and the ligands that bind to them has led to **rational drug design**, in which *computer modeling of enzyme-ligand interactions* replaces much of the initial chemical synthesis and clinical prescreening of potential therapeutic agents, saving much time and effort in drug development.

cGMP

Viagra

Note the structural similarity between cGMP (left) and Viagra (right).

2. The other general possibility is that one substrate, A, binds to the enzyme and reacts with it to yield a chemically modified form of the enzyme (E') plus the product, P. The second substrate, B, then reacts with E' , regenerating E and forming the other product, Q.

Reactions that fit this model are called **ping-pong** or **double-displacement reactions**. Two distinctive features of this mechanism are the obligatory formation of a modified enzyme intermediate, E' , and the pattern of parallel lines obtained in double-reciprocal plots of the rates observed with different fixed concentrations of one substrate (B) versus a series of concentrations of A (see Figure 13.22).

13.5a The Conversion of AEB to PEQ Is the Rate-Limiting Step in Random, Single-Displacement Reactions

In this type of sequential reaction, all possible binary enzyme–substrate complexes (AE, EB, PE, EQ) are formed rapidly and reversibly when the enzyme is added to a reaction mixture containing A, B, P, and Q:

The rate-limiting step is the reaction $AEB \rightarrow PEQ$. It does not matter whether A or B binds first to E, or whether Q or P is released first from QEP. Sometimes, reactions that follow this random order of addition of substrates to E can be distinguished from reactions obeying an ordered, single-displacement mechanism. If A has *no* influence on the binding constant for B (and vice versa) and the mechanism is purely random, the lines in a Lineweaver–Burk plot intersect at the $1/[A]$ axis (Figure 13.20).

Figure 13.20 Random, single-displacement bisubstrate mechanism where A does not affect B binding, and vice versa.

Creatine

Creatine-P

Figure 13.21 The structures of creatine and creatine phosphate (Creatine-P), guanidinium compounds that are important in muscle energy metabolism.

Creatine Kinase Acts by a Random, Single-Displacement Mechanism An example of a random, single-displacement mechanism is seen in the enzyme creatine kinase, a phosphoryl transfer enzyme that uses ATP as a phosphoryl donor to form creatine phosphate (CrP) from creatine (Cr). Creatine-P is an important reservoir of phosphate-bond energy in muscle cells (Figure 13.21).

The overall direction of the reaction will be determined by the relative concentrations of ATP, ADP, Cr, and CrP and the equilibrium constant for the reaction. The enzyme can be considered to have two sites for substrate (or product) binding: an adenine nucleotide site, where ATP or ADP binds, and a creatine site, where Cr or CrP is bound. In such a mechanism, ATP and ADP compete for binding at their unique site, and Cr and CrP compete at the specific Cr/CrP-binding site. Note that no modified enzyme form (E'), such as an E-P intermediate, appears here. The reaction is characterized by rapid and reversible binary ES complex formation, followed by addition of the remaining substrate, and the rate-determining reaction taking place within the ternary complex.

13.5b In an Ordered, Single-Displacement Reaction, the Leading Substrate Must Bind First

In an ordered reaction, the **leading substrate**, A (also called the **obligatory** or **compulsory substrate**), must bind first. Then the second substrate, B, binds. B cannot bind to free enzyme in the absence of A. The reaction between A and B occurs in the ternary complex and is usually followed by an ordered release of the products of the reaction, P and Q. In the following diagrams, P is the product of A and is released last. One representation, suggested by W. W. Cleland, is as follows:

Another way of portraying this mechanism is as follows:

Note that A and P are competitive for binding to the free enzyme, E, but not A and B (or P and B).

NAD⁺-Dependent Dehydrogenases Show Ordered Single-Displacement Mechanisms

Nicotinamide adenine dinucleotide (NAD⁺)-dependent dehydrogenases are enzymes that typically behave according to the kinetic pattern just described. A general reaction of these dehydrogenases is

The leading substrate (A) is nicotinamide adenine dinucleotide (NAD^+), and NAD^+ and NADH (product P) compete for a common site on E. A specific example is offered by alcohol dehydrogenase (ADH):

We can verify that this ordered mechanism is not random by demonstrating that no B (ethanol) is bound to E in the absence of A (NAD^+).

13.5c Double-Displacement (Ping-Pong) Reactions Proceed Via Formation of a Covalently Modified Enzyme Intermediate

Double-displacement reactions are characterized by a pattern of parallel lines when $1/v$ is plotted as a function of $1/[A]$ at different concentrations of B, the second substrate (Figure 13.22). Reactions conforming to this kinetic pattern are characterized by the fact that the product of the enzyme's reaction with A (called P in the following schemes) is released *prior* to reaction of the enzyme with the second substrate, B. As a result of this process, the enzyme, E, is converted to a modified form, E', which then reacts with B to give the second product, Q, and regenerate the unmodified enzyme form, E:

Double-reciprocal form of the rate equation: $\frac{1}{v} = \frac{K_m^A}{V_{\max}} \left(\frac{1}{[A]} \right) + \left(1 + \frac{K_m^B}{[B]} \right) \left(\frac{1}{V_{\max}} \right)$

Figure 13.22 Double-displacement (ping-pong) bisubstrate mechanisms are characterized by parallel lines in plots of $1/v$ vs. $1/[A]$.

or

Note that these schemes predict that A and Q compete for the free enzyme form, E, while B and P compete for the modified enzyme form, E'. A and Q do not bind to E', nor do B and P combine with E.

Aminotransferases Show Double-Displacement Catalytic Mechanisms One class of enzymes that follow a ping-pong-type mechanism are *aminotransferases* (previously known as transaminases). These enzymes catalyze the transfer of an amino group from an amino acid to an α -keto acid. The products are a new amino acid and the keto acid corresponding to the carbon skeleton of the amino donor:

A specific example is *glutamate:aspartate aminotransferase*. Figure 13.23 depicts the scheme for this mechanism. Note that glutamate and aspartate are competitive for E and that oxaloacetate and α -ketoglutarate compete for E'. In glutamate:aspartate aminotransferase, an enzyme-bound coenzyme, *pyridoxal phosphate* (a vitamin B₆ derivative), serves as the amino group acceptor/donor in the enzymatic reaction. The unmodified enzyme, E, has the coenzyme in the aldehydic pyridoxal form, whereas in the modified enzyme, E', the coenzyme is actually pyridoxamine phosphate (Figure 13.23). Not all enzymes displaying ping-pong-type mechanisms require coenzymes as carriers for the chemical substituent transferred in the reaction.

Figure 13.23 Glutamate:aspartate aminotransferase, an enzyme conforming to a double-displacement bisubstrate mechanism.

13.5d Exchange Reactions Are One Way to Diagnose Bisubstrate Mechanisms

A number of diagnostic tests are necessary for the assignment of a reaction mechanism to a specific enzyme. One is the graphic analysis of the kinetic patterns observed. It is usually easy to distinguish between single- and double-displacement reactions in this manner, and examining competitive effects between substrates aids in assigning reactions to random versus ordered patterns of S binding. A second diagnostic test is to determine whether the enzyme catalyzes an **exchange reaction**: a double-displacement reaction where the chemical group transferred from a substrate S to E to form E' is transferred back to a different molecule of the same substrate. Consider, as an example, the two enzymes *sucrose phosphorylase* and *maltose phosphorylase*. Both catalyze the phosphorolysis of a disaccharide and both yield glucose-1-phosphate and a free hexose:

Interestingly, in the absence of sucrose and fructose, sucrose phosphorylase will catalyze the exchange of inorganic phosphate, P_i , into glucose-1-phosphate. This reaction can be followed by using $^{32}\text{P}_i$ as a radioactive tracer and observing the incorporation of ^{32}P into glucose-1-phosphate:

Maltose phosphorylase cannot carry out a similar reaction. The ^{32}P exchange reaction of sucrose phosphorylase is accounted for by a double-displacement mechanism where E' is E-glucose:

Thus, in the presence of just $^{32}\text{P}_i$ and glucose-1-phosphate, sucrose phosphorylase still catalyzes the second reaction and radioactive P_i is incorporated into glucose-1-phosphate over time.

Maltose phosphorylase proceeds via a single-displacement reaction that necessarily requires the formation of a ternary maltose:E: P_i (or glucose:E:glucose-1-phosphate) complex for any reaction to occur. Exchange reactions are a characteristic of enzymes that obey double-displacement mechanisms at some point in their catalysis.

13.5e Multisubstrate Reactions Can Also Occur in Cells

Thus far, we have considered enzyme-catalyzed reactions involving one or two substrates. How are the kinetics described in those cases in which more than two substrates participate in the reaction? An example is the glycolytic enzyme *glyceraldehyde-3-phosphate dehydrogenase*:

Many other multisubstrate examples abound in metabolism. These situations are managed by realizing that the interaction of the enzyme with its many substrates can be treated as a series of unisubstrate or bisubstrate steps in a multistep reaction pathway. Thus, the complex mechanism of a multisubstrate reaction is resolved into a sequence of steps, each of which obeys the single- and double-displacement patterns just discussed.

13.6 | How Can Enzymes Be So Specific?

The extraordinary ability of an enzyme to catalyze only one particular reaction is a quality known as **specificity**. Specificity means an enzyme acts only on a specific substance, its substrate, invariably transforming it into a specific product. That is, an enzyme binds only certain compounds, and then, only a specific reaction ensues.

Some enzymes show absolute specificity, catalyzing the transformation of only one specific substrate to yield a unique product. Other enzymes carry out a particular reaction but act on a class of compounds. For example, *hexokinase* (ATP:hexose-6-phosphotransferase) will carry out the ATP-dependent phosphorylation of a number of hexoses at the 6-position, including glucose. Specificity studies on enzymes entail an examination of the rates of the enzymatic reaction obtained with various **structural analogs** of the substrate. By determining which functional and structural groups within the substrate affect binding or catalysis, enzymologists can map the properties of the active site, analyzing questions such as: Can the active site accommodate sterically bulky groups? Are ionic interactions between E and S important? Are H bonds formed?

13.6a The Lock-and-Key Hypothesis Was the First Explanation for Specificity

Pioneering enzyme specificity studies at the turn of the twentieth century by the great organic chemist Emil Fischer led to the notion of an enzyme resembling a lock and its particular substrate the key. This analogy captures the essence of the specificity that exists between an enzyme and its substrate, but enzymes are not rigid templates like locks.

13.6b The Induced-Fit Hypothesis Provides a More Accurate Description of Specificity

New ideas do not always gain immediate acceptance: "Although we did many experiments that in my opinion could only be explained by the induced-fit theory, gaining acceptance for the theory was still an uphill fight. One (journal) referee wrote, 'The Fischer Key-Lock theory has lasted 100 years and will not be overturned by speculation from an embryonic scientist.'" *Daniel Koshland, 1996. How to get paid for having fun. Annual Review of Biochemistry* **65**:1–13.

Enzymes are highly flexible, conformationally dynamic molecules, and many of their remarkable properties, including substrate binding and catalysis, are due to their structural pliancy. Realization of the conformational flexibility of proteins led Daniel Koshland to hypothesize that the binding of a substrate by an enzyme is an interactive process. That is, the shape of the enzyme's active site is actually modified upon binding S, in a process of dynamic recognition between enzyme and substrate aptly called **induced fit**. In essence, substrate binding alters the conformation of the protein so that the protein and the substrate fit each other more precisely. The process is truly interactive in that the conformation of the substrate also changes as it adapts to the conformation of the enzyme. Indeed, this substrate-induced conformational change is key to enzyme specificity. Substrate specificity is ultimately determined by two factors: (1) weak binding of S to E, and (2) the rate of the substrate-induced conformational change leading to the closed, catalytically competent state.

This idea also helps explain some of the mystery surrounding the enormous catalytic power of enzymes: In enzyme catalysis, precise orientation of catalytic residues comprising the active site is necessary for the reaction to occur; substrate binding induces this precise orientation by the changes it causes in the protein's conformation.

13.6c Induced Fit Favors Formation of the Transition State

The catalytically active enzyme substrate complex is an interactive structure in which the enzyme causes the substrate to adopt a form that mimics the transition state of the reaction. Thus, a poor substrate would be one that was less effective in directing the formation of an optimally active enzyme:transition state conformation. This active conformation of the enzyme molecule is thought to be relatively unstable in the absence of substrate, and free enzyme thus reverts to a different conformational state.

13.6d Specificity and Reactivity

Consider, for example, why hexokinase catalyzes the ATP-dependent phosphorylation of hexoses such as glucose but not smaller phosphoryl-group acceptors such as glycerol, ethanol, or even water. Surely these smaller compounds are not sterically forbidden from approaching the active site of hexokinase (Figure 13.24). Indeed, water should penetrate the active site easily and serve as a highly effective phosphoryl-group acceptor. Accordingly, hexokinase should display high ATPase activity. It does not. Only the

Figure 13.24 A drawing, roughly to scale, of H_2O , glycerol, glucose, and an idealized hexokinase molecule. Only glucose will trigger a conformational change in hexokinase, even though the glycerol and water, as smaller molecules, are not sterically excluded from the active-site cleft.

binding of hexoses induces hexokinase to assume its fully active conformation. The hexose-binding site of hexokinase is located between two protein domains. Binding of glucose in the active site induces a conformational change in hexokinase that causes the two domains to close upon one another, creating the catalytic site.

13.7 | Are All Enzymes Proteins?

Thus far, the discussion has assumed that enzymes are proteins. The traditional view of enzymes as proteins did not anticipate that the antibody family of proteins might include members with catalytic activity. Even more surprising was the discovery of catalytic RNAs.

13.7a RNA Molecules That Are Catalytic Have Been Termed Ribozymes

It was long assumed that all enzymes are proteins. However, in the early 1980s, instances of biological catalysis by RNA molecules were discovered. Catalytic RNAs, or **ribozymes**, satisfy several enzymatic criteria: They are substrate specific, they enhance the reaction rate, and they emerge from the reaction unchanged. Most ribozymes act in RNA processing, cutting the phosphodiester backbone at specific sites and religating needed segments to form functional RNA strands while discarding extraneous pieces. For example, bacterial RNase P is a ribozyme involved in the formation of mature tRNA molecules from longer RNA transcripts. RNase P requires an RNA component and a protein subunit for its activity in the cell. In vitro, the protein alone is incapable of catalyzing the maturation reaction, but the RNA component by itself can carry out the reaction under appropriate conditions. As another example, the introns within some rRNAs and mRNAs are ribozymes that can catalyze their own excision from large RNA transcripts by a process known as **self-splicing**. For instance, in the ciliated protozoan *Tetrahymena*, formation of mature ribosomal RNA from a pre-rRNA precursor involves the removal of an internal RNA segment and the joining of the two ends. The excision of this intron and ligation of the exons is catalyzed by the intron itself, in the presence of Mg^{2+} and a free molecule of guanine nucleoside or nucleotide (Figure 13.25). In vivo, the intervening sequence RNA probably acts only in splicing itself out; in vitro, however, it can act many times, turning over like a true enzyme.

The Ribosome Is a Ribozyme A particularly significant case of catalysis by RNA occurs in protein synthesis. The **peptidyl transferase reaction**, which is the reaction of peptide bond formation during protein synthesis, is catalyzed by the large rRNA of the large ribosomal subunit. The substrates for the peptidyl transferase reaction are two tRNA

Figure 13.25 RNA splicing in *Tetrahymena* rRNA maturation: (a) the guanosine-mediated reaction involved in the autocatalytic excision of the *Tetrahymena* rRNA intron and (b) the overall splicing process. The cyclized intron is formed via nucleophilic attack of the freed 3'-OH end of the intron on the phosphodiester bond that is 15 nucleotides from the 5'-GA end of the spliced-out intron. Cyclization frees a linear 15-mer with a 5'-GA end.

molecules, one bearing the growing peptide chain (the *peptidyl-tRNA_P*) and the other bearing the next amino acid to be added (the *aminoacyl-tRNA_A*). Both the peptidyl chain and the amino acid are attached to their respective tRNAs via ester bonds to the O atom at the CCA-3' ends of these tRNAs (see Figure 11.35). Base-pairing between these C residues in the two tRNAs and G residues in the 23S rRNA position the substrates for the reaction to occur (Figure 13.26). The two Cs at the peptidyl-tRNA_P CCA end pair with G2251 and G2252 of the 23S rRNA, and the last C (C75) at the 3'-end of the aminoacyl-tRNA_A pairs with G2553. The 3'-terminal A of the aminoacyl-tRNA_A interacts with G2583, and the terminal A of the peptidyl-tRNA_P binds to A2450. Addition of the incoming amino acid to the peptidyl chain occurs when the α -amino group of the aminoacyl-tRNA_A makes a nucleophilic attack on the carbonyl C linking the peptidyl chain to its tRNA_P. Specific 23S rRNA bases and ribose-OH groups facilitate this nucleophilic attack by favoring proton abstraction from the aminoacyl α -amino group (Figure 13.27). The products of this reaction are a one-residue-longer peptidyl chain attached to the tRNA_A and the empty tRNA_P.

The fact that RNA can catalyze such important reactions is experimental support for the idea that a primordial world dominated by RNA molecules existed before the evolution of DNA and proteins. Sidney Altman and Thomas R. Cech shared the 1989 Nobel Prize in Chemistry for their discovery of the catalytic properties of RNA.

13.7b Antibody Molecules Can Have Catalytic Activity

Antibodies are *immunoglobulins*, which are proteins. Catalytic antibodies are antibodies with catalytic activity (catalytic antibodies are also called **abzymes**, a word created by combining “Ab,” the abbreviation for antibody, with enzyme.) Like other antibodies, catalytic antibodies are elicited in an organism in response to immunological challenge by a foreign molecule called an **antigen**. To trigger production of an antibody displaying catalytic activity, the antigen is purposefully engineered to be *an analog of the transition state in a reaction*. The strategy is based on the idea that a protein specific for binding the transition state of a reaction will promote entry of the normal reactant into the reactive, transition-state conformation. Thus, a catalytic antibody facilitates, or catalyzes, a reaction by forcing the conformation of

Figure 13.26 Structure of the 50S ribosomal subunit. (a) Molecular graphic of the 50S subunit from *Haloarcula marismortui* (PDB id = 1FFK). Ribosomal proteins are shown in blue, the large 23S rRNA backbone in brown, the 5S rRNA backbone in olive, and a tRNA substrate analog in red. The tRNA analog identifies the peptidyl transferase catalytic center of the 50S subunit. (b) The aminoacyl-tRNA_A (yellow) and the peptidyl-tRNA_P (orange) in the peptidyl transferase active site. Bases of the 23S rRNA shown in green and labeled according to their position in the 23S rRNA sequence. Interactions between the tRNAs and the 23S rRNA are indicated by dotted lines. The α -amino group of the aminoacyl-tRNA_A (blue) is positioned for the attack on the carbonyl-C (green) of the peptidyl-tRNA_P. (Adapted from Figure 2 in Beringer, M., and Rodnina, M. V., 2007. The ribosomal peptidyl transferase. *Molecular Cell* 26:311–321.)

Figure 13.27 The peptidyl transferase reaction. Abstraction of an amide proton from the α -amino group of the aminoacyl-tRNA_A (red) by the 2'-O of the terminal A of the peptidyl-tRNA_P (blue) is aided by hydrogen-bonding interactions with neighboring 23S rRNA nucleotides (green). These interactions facilitate nucleophilic attack by the α -amino group of the aminoacyl-tRNA_A on the carbonyl C of the peptidyl-tRNA_P and peptide bond formation between the incoming amino acid and the growing peptide chain to give a one-residue-longer peptide chain attached to the tRNA_A. (Adapted from Figure 3 in Beringer, M., and Rodnina, M. V., 2007. The ribosomal peptidyl transferase. *Molecular Cell* 26:311–321.)

its substrate in the direction of its transition state. (A prominent explanation for the remarkable catalytic power of conventional enzymes is their great affinity for the transition state in the reactions they catalyze.)

One proof of this principle has been to prepare ester analogs by substituting a phosphorus atom for the carbon in the ester group (Figure 13.28). The phosphonate compound mimics the natural transition state of ester hydrolysis, and antibodies elicited against these analogs act like enzymes in accelerating the rate of ester hydrolysis as much as 1000-fold. Abzymes have been developed for a number of other classes of reactions, including C—C bond formation via aldol condensation (the reverse of the aldolase reaction [see Figure 13.2, reaction 4]) and the pyridoxal 5'-P-dependent aminotransferase reaction shown in Figure 13.23. Abzyme biotechnology is one way to create designer enzymes that catalyze desired chemical reactions.

Catalytic antibodies also occur naturally. Autoimmune diseases are diseases that arise because an individual begins to produce antibodies against one of their own cellular constituents. Multiple sclerosis (MS), one such autoimmune disease, is characterized by gradual destruction of the myelin sheath surrounding neurons throughout the brain and spinal cord. Blood serum obtained from some MS patients contains antibodies capable of carrying out the proteolytic destruction of myelin basic protein (MBP). That is, these

Figure 13.28 Creation of an abzyme antigen by modeling the transition state of a reaction. The transition-state analog will trigger formation of an abzyme if it is antigenic. **(a)** The intramolecular hydrolysis of a hydroxy ester to yield as products a δ -lactone and the alcohol phenol. Note the cyclic transition state. **(b)** The cyclic phosphonate ester analog of the cyclic transition state.

antibodies were MBP-destructive proteases. Similarly, hemophilia A is a blood-clotting disorder due to lack of the factor VIII, an essential protein for formation of a blood clot. Serum from some sufferers of hemophilia A contained antibodies with proteolytic activity against factor VIII. Thus, some antibodies are proteases.

13.8 | Is It Possible to Design an Enzyme to Catalyze Any Desired Reaction?

Enzymes have evolved to catalyze metabolic reactions with high selectivity, specificity, and rate enhancements. Given these remarkable attributes, it would be very desirable to have the ability to create **designer enzymes** individually tailored to catalyze any imaginable reaction, particularly those that might have practical uses in industrial chemistry, the pharmaceutical industry, or environmental remediation. To this end, several approaches have been taken to create a desired enzyme *de novo* (literally “anew” or “from scratch.” In biochemistry, the synthesis of some end product from simpler precursors.) Most approaches begin with a known enzyme and then engineer it using *in vitro* mutagenesis (see Chapter 12) to replace active-site residues with a new set that might catalyze the desired reaction. This strategy has the advantage that the known protein structure provides a stable scaffold into which a new catalytic site can be introduced. As pointed out in Chapter 6, despite the extremely large number of possible amino acid sequences for a polypeptide chain, the number of stable tertiary structures that proteins can adopt is rather limited. Yet proteins have an extraordinary range of functional possibilities. So, this approach is rational. A second, more difficult, approach attempts the completely new design of a protein with the desired structure and activity. Often, this approach relies on *in silico* methods, where the spatial and reactive properties of its putative active site are modeled, refined, and optimized via computer. Although this approach has fewer limitations in terms of size and shape of substrates, it brings other complications, such as the design of a proper protein scaffold for the active site, protein folding, and protein stability, to say nothing of the difficulties of going from the computer model (in *silico*) to a real enzyme in a cellular environment (in *vivo*). Nevertheless, computer design of enzymes with k_{cat}/K_m ratios greater than $10^5 \text{ M}^{-1}\text{s}^{-1}$ has been achieved. The Rosetta protein modeling suite is popular software for such *in silico* enzyme design.

Enzymes have shown adaptability over the course of evolution. New enzyme functions have appeared time and time again, as mutation and selection according to Darwinian principles operate on existing enzymes. Some enzyme designers have coupled natural evolutionary processes with rational design using *in vitro* mutagenesis. Expression of mutated

versions of the gene encoding the enzyme in bacteria, followed by rounds of selection for bacteria producing an enzyme with even better catalytic properties, takes advantage of naturally occurring processes to drive further mutation and selection for an optimal enzyme. This dual approach is whimsically referred to as *semirational design* because it relies on the rational substitution of certain amino acids with new ones in the active site, followed by directed evolution (selection for bacteria expressing more efficient versions of the enzyme).

13.8a A Designer Enzyme for Bioremediation

An example of active-site engineering is the site-directed mutation of an epoxide hydrolase to change its range of substrate selection so that it now acts on chlorinated epoxides (Figure 13.29). Degradation of chlorinated epoxides is a major problem in the removal of toxic pollutants from water resources. Mutation of a bacterial epoxide hydrolase at three active-site residues (F¹⁰⁸, I²¹⁹, and C²⁴⁸) and selection in bacteria for enhanced chlorinated epoxide hydrolase activity yielded an F108L/I219L/C248I mutant enzyme that catalyzed the conversion of *cis*-dichloroepoxyethane to Cl[−] ions and glyoxal with a dramatically increased $V_{\max}/K_m$ ratio.

13.8b A Case Study for Designer Enzyme Development – Kemp Eliminases

A model reaction favored by scientists exploring the fundamental properties of enzyme catalysis and the creation of designer enzymes is the Kemp elimination reaction (Figure 13.30). The basic design strategy is to test various protein structures, such as the TIM α/β -barrel (see Figure 6.34d) as scaffolds on which to construct a Kemp eliminase (KE) active site. Different active-site bases (B: [−]) are then tested in such model systems, such as a carboxylate group of an aspartate or glutamate side chain. A refinement of this approach is to position the imidazole group of a histidine side chain near the catalytic D (or E) carboxylate to form an active-site His-Asp (or Glu) dyad. Using computational enzyme design algorithms and close observation of protein structural changes within the active site introduced during directed evolution, KE designer enzymes have been created that show more than a 700-fold increase in catalytic activity over earlier versions.

Figure 13.29 *cis*-1,2-Dichloroethylene (DCE) is an industrial solvent that poses hazards to human health; DCE occurs as a pollutant in water sources. Bacterial metabolism of DCE to form *cis*-1,2-dichloroepoxyethane (step 1) occurs readily, but enzymatic degradation of the epoxide to glyoxal and chloride ions (step 2) is limited. Microbial detoxification of DCE in ground water requires enzymes for both steps 1 and 2. Genetic engineering of an epoxide hydrolase to create an enzyme capable of using *cis*-1,2-dichloroepoxyethane as a substrate and catalyzing step 2 is a practical example of de novo enzyme design.

Figure 13.30 The Kemp elimination reaction occurs when a catalytic base (B: [−]) abstracts a proton from a benzisoxazole ring, leading to the opening of the isoxazole ring and formation of *o*-cyanophenolate. X is typically a nitro (−NO₂) group, so the substrate is 5-nitrobenzisoxazole.

Foundational Biochemistry Things You Should Know after Reading Chapter 13.

- Enzymes are the agents of metabolic function.
- Enzymes exert kinetic control over thermodynamic potentiality.
- Living systems use enzymes to accelerate and control the rates of vitally important biochemical reactions.
- Catalytic power is defined as the ratio of the enzyme-catalyzed rate of a reaction to the uncatalyzed rate.
- The substance upon which an enzyme acts is termed the substrate of the enzyme.
- Specificity is the term used to define the selectivity of enzymes for their substrates.
- The specific site on the enzyme to which the substrate binds and where catalysis occurs is called the active site.
- Regulation of enzyme activity ensures that the rate of a metabolic reaction is appropriate to cellular requirements.
- Enzyme nomenclature provides a systematic way of naming metabolic reactions.
- Coenzymes and cofactors are nonprotein components of enzymes that are essential for enzyme activity.
- Tightly bound coenzymes are termed prosthetic groups; the protein without the prosthetic group is called an apoenzyme.
- Enzyme kinetics is the branch of science that studies the properties of enzyme-catalyzed reactions.
- Enzymes, like other catalysts, lower the free energy of activation for a reaction.
- Decreasing the free energy of activation, $\Delta G^\ddagger$, increases reaction rate.
- The rate of a simple enzyme-catalyzed reaction can be described by the Michaelis–Menten equation.
- The Briggs–Haldane steady-state assumption ($d[\text{ES}]/dt = 0$) provides an improved interpretation of the Michaelis–Menten equation.
- K_m , the Michaelis constant, is defined as $(k_{-1} + k_2)/k_1$.
- The velocity of the reaction, v , is given by $v = d[\text{P}]/dt = k_2[\text{ES}]$.
- The maximal velocity of the reaction, $V_{\max}$, is achieved when all of the enzyme, E, is in the ES form. $V_{\max} = k_2[\text{E}_T]$.
- When $[\text{S}] = K_m$, $v = V_{\max}/2$.
- The turnover number, or molecular activity, of an enzyme is defined as k_{cat} : $k_{\text{cat}} = V_{\max}/[\text{E}_T]$.
- The catalytic efficiency of an enzyme is defined as k_{cat}/K_m .
- The catalytic efficiency of an enzyme cannot exceed the diffusion-controlled rate of encounters between E and S. Thus, the upper limit on k_{cat}/K_m is about $10^9 \text{ M}^{-1}\text{s}^{-1}$.
- Lineweaver–Burk double-reciprocal ($1/v$ vs. $1/[\text{S}]$) plots and Hanes–Woolf ($[\text{S}]/v$ vs. $[\text{S}]$) plots convert the hyperbolic Michaelis–Menten v vs. $[\text{S}]$ response into a straight line.
- Enzyme activity is affected by pH, temperature, and ionic strength, all of which can affect protein conformation.
- Enzyme inhibitors are useful probes of the properties of enzymatic reactions.
- Many drugs and other pharmacological agents are enzyme inhibitors.
- Enzyme inhibitors are classified as competitive (compete with S for binding to the active site), noncompetitive (bind elsewhere on the enzyme), or uncompetitive (bind only to the ES complex).
- Irreversible inhibitors bind irreversibly to or form covalent bonds with the enzyme.
- Bisubstrate reaction mechanisms may be single-displacement (both substrates bind and then the reaction occurs) or double-displacement (the first substrate binds, reaction occurs, product is released, and then the second substrate binds, further reaction occurs, and the second product is released).
- Single-displacement reactions may be random (it does not matter which substrate binds first) or ordered (one substrate, called the leading substrate, binds first; only when it is bound can the second substrate bind).
- Fischer’s lock-and-key hypothesis was the original explanation for enzyme specificity.
- Koshland’s induced-fit hypothesis is a better explanation of enzyme specificity because it considers the conformational change induced in the enzyme (and the substrate) when S is bound by E.
- Not only protein molecules but RNA molecules may be catalytic; catalytic RNA molecules are termed ribozymes.
- The ribosome is a ribozyme.
- Antibodies that have catalytic activity are called abzymes.
- Designer enzymes are enzymes engineered to catalyze a reaction for which no naturally occurring enzyme exists.
- Several approaches have been taken to create designer enzymes: rational enzyme design (altering the active site of a known enzyme so that it now catalyzes a new reaction) or in silico design (using computers to model an active site that will catalyze a desired reaction and then attempting to create a protein that will have such an active site).
- Designer enzymes have potential applications in organic synthesis (such as the synthesis of new drugs) and environmental remediation (to remove pollutants).

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. **Understanding K_m** The activity of two enzymes was studied using different carbohydrates as their substrate. The table shows the results. How do those two enzymes compare?

	D-glucose	D-fructose	D-ribose	D-mannose	D-galactose
Enzyme A	$K_m = 0.25$ mM	$K_m = 0.20$ mM	$K_m = 9.8$ mM	$K_m = 0.21$ mM	$K_m = 0.22$ mM
Enzyme B	$K_m = 7.02$ mM	$K_m = 6.95$ mM	$K_m = 0.05$ mM	$K_m = 7.25$ mM	$K_m = 7.8$ mM

2. **Exploring the Michaelis–Menten Equation - I** According to the Michaelis–Menten equation, what is the $v/V_{\max}$ ratio when $[S] = 4 K_m$?
3. **Exploring the Michaelis–Menten Equation - II** If $V_{\max} = 100 \mu\text{mol/mL} \cdot \text{s}$ and $K_m = 2 \text{ mM}$, what is the velocity of the reaction when $[S] = 20 \text{ mM}$?
4. **Exploring the Michaelis–Menten Equation - III** For a Michaelis–Menten reaction, $k_1 = 7 \times 10^7/\text{M} \cdot \text{s}$, $k_{-1} = 1 \times 10^3/\text{s}$, and $k_2 = 2 \times 10^4/\text{s}$. What are the values of K_S and K_m ? Does substrate binding approach equilibrium, or does it behave more like a steady-state system?
5. **Graphing the Results from Kinetics Experiments with Enzyme Inhibitors** The following kinetic data were obtained for an enzyme in the absence of any inhibitor (1) and in the presence of two different inhibitors (2) and (3) at 5 mM concentration. Assume $[E_T]$ is the same in each experiment.

[S] (mM)	(1) v ($\mu\text{mol}/$ $\text{mL} \cdot \text{s}$)	(2) v ($\mu\text{mol}/$ $\text{mL} \cdot \text{s}$)	(3) v ($\mu\text{mol}/$ $\text{mL} \cdot \text{s}$)
1	12	4.3	5.5
2	20	8	9
4	29	14	13
8	35	21	16
12	40	26	18

Graph these data as Lineweaver–Burk plots and use your graph to find answers to a. and b.

- a. Determine $V_{\max}$ and K_m for the enzyme.
- b. Determine the type of inhibition and the K_i for each inhibitor.
6. **Calculating K_i and K_i'** The enzymatic activity of an enzyme was studied in the presence of mixed noncompetitive inhibitors A and B. The results for inhibitor A (tested at $50 \mu\text{M}$) are shown in the Lineweaver–Burk format. The results for inhibitor B (tested at $15 \mu\text{M}$) are shown in the Hanes–Woolf format. Calculate K_i and K_i' for each inhibitor.

7. **How Varying the Amount of Enzyme or the Addition of Inhibitors Affects v versus $[S]$ Plots** Using Figure 13.7 as a model, draw curves that would be obtained in v versus $[S]$ plots when
- twice as much enzyme is used.
 - half as much enzyme is used.
 - a competitive inhibitor is added.
 - a pure noncompetitive inhibitor is added.
 - an uncompetitive inhibitor is added.

For each example, indicate how $V_{\max}$ and K_m change.

8. **Using Graphical Methods to Derive the Kinetic Constants for an Ordered, Single-Displacement Reaction** The general rate equation for an ordered, single-displacement reaction where A is the leading substrate is

$$v = \frac{V_{\max}[A][B]}{(K_S^A K_m^B + K_m^A[B] + K_m^B[A] + [A][B])}$$

Write the Lineweaver–Burk (double-reciprocal) equivalent of this equation and from it calculate algebraic expressions for the following:

- the slope
 - the y-intercepts
 - the horizontal and vertical coordinates of the point of intersection when $1/v$ is plotted versus $1/[B]$ at various fixed concentrations of A
9. **Interpreting Kinetics Experiments from Graphical Patterns** The following graphical patterns obtained from kinetic experiments have several possible interpretations depending on the nature of the experiment and the variables being plotted. Give at least two possibilities for each.

10. **Using the Equations of Enzyme Kinetics to Treat Methanol Intoxication** Liver alcohol dehydrogenase (ADH) is relatively nonspecific and will oxidize ethanol or other alcohols, including methanol. Methanol oxidation yields formaldehyde, which is quite toxic, causing, among other things, blindness. Mistaking it for the cheap wine he usually prefers, my dog Clancy ingested about 50 mL

of windshield washer fluid (a solution 50% in methanol). Knowing that methanol would be excreted eventually by the dog's kidneys if its oxidation could be blocked, and realizing that, in terms of methanol oxidation by ADH, ethanol would act as a competitive inhibitor, I offered him some wine. How much (12% ethanol) must he consume in order to lower the activity of his ADH on methanol to 5% of its normal value if the K_m values of canine ADH for ethanol and methanol are 1 millimolar and 10 millimolar, respectively? (The K_I for ethanol in its role as competitive inhibitor of methanol oxidation by ADH is the same as its K_m .) Both the methanol and ethanol will quickly distribute throughout Clancy's body fluids, which amount to about 15 L. Assume the densities of 50% methanol and the wine are both 0.9 g/mL.

- 11. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - I** Measurement of the rate constants for a simple enzymatic reaction obeying Michaelis–Menten kinetics gave the following results:

$$k_1 = 2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$$

$$k_{-1} = 1 \times 10^3 \text{ s}^{-1}$$

$$k_2 = 5 \times 10^3 \text{ s}^{-1}$$

- What is K_S , the dissociation constant for the enzyme–substrate complex?
- What is K_m , the Michaelis constant for this enzyme?
- What is k_{cat} (the turnover number) for this enzyme?
- What is the catalytic efficiency (k_{cat}/K_m) for this enzyme?
- Does this enzyme approach “kinetic perfection”? (That is, does k_{cat}/K_m approach the diffusion-controlled rate of enzyme association with substrate?)
- If a kinetic measurement was made using 2 nanomoles of enzyme per mL and saturating amounts of substrate, what would V_{max} equal?
- Again, using 2 nanomoles of enzyme per mL of reaction mixture, what concentration of substrate would give $v = 0.75 V_{max}$?
- If a kinetic measurement was made using 4 nanomoles of enzyme per mL and saturating amounts of substrate, what would V_{max} equal? What would K_m equal under these conditions?

- 12. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - II** Triose phosphate isomerase catalyzes the conversion of glyceraldehyde-3-phosphate to dihydroxyacetone phosphate.

The K_m of this enzyme for its substrate glyceraldehyde-3-phosphate is $1.8 \times 10^{-5} \text{ M}$. When $[\text{glyceraldehydes-3-phosphate}] = 30 \mu\text{M}$, the rate of the reaction, v , was $82.5 \mu\text{mol mL}^{-1} \text{ s}^{-1}$.

- What is V_{max} for this enzyme?
- Assuming 3 nanomoles per mL of enzyme was used in this experiment ($[E_{total}] = 3 \text{ nanomol/mL}$), what is k_{cat} for this enzyme?
- What is the catalytic efficiency (k_{cat}/K_m) for triose phosphate isomerase?
- Does the value of k_{cat}/K_m reveal whether triose phosphate isomerase approaches catalytic perfection?
- What determines the ultimate speed limit of an enzyme-catalyzed reaction? That is, what is it that imposes the physical limit on kinetic perfection?

- 13. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - III** The citric acid cycle enzyme *fumarase* catalyzes the conversion of fumarate to form malate.

The turnover number, k_{cat} , for fumarase is 800/s. The K_m of fumarase for its substrate fumarate is $5 \mu\text{M}$.

- In an experiment using 2 nanomole/mL of fumarase, what is V_{max} ?
- The cellular concentration of fumarate is $47.5 \mu\text{M}$. What is v when $[\text{fumarate}] = 47.5 \mu\text{M}$?
- What is the catalytic efficiency of fumarase?
- Does fumarase approach catalytic perfection?

- 14. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - IV** Carbonic anhydrase catalyzes the hydration of CO_2 :

The K_m of carbonic anhydrase for CO_2 is 12 mM. Carbonic anhydrase gave an initial velocity $v_o = 4.5 \mu\text{mol H}_2\text{CO}_3 \text{ formed/mL} \cdot \text{s}$ when $[\text{CO}_2] = 36 \text{ mM}$.

- What is V_{max} for this enzyme?
- Assuming 5 pmol/mL ($5 \times 10^{-12} \text{ moles/mL}$) of enzyme were used in this experiment, what is k_{cat} for this enzyme?
- What is the catalytic efficiency of this enzyme?
- Does carbonic anhydrase approach catalytic perfection?

- 15. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - V** Acetylcholinesterase catalyzes the hydrolysis of the neurotransmitter acetylcholine:

The K_m of acetylcholinesterase for its substrate acetylcholine is $9 \times 10^{-5} \text{ M}$. In a reaction mixture containing 5 nanomoles/mL of acetylcholinesterase and 150 μM acetylcholine, a velocity $v_o = 40 \mu\text{mol/mL} \cdot \text{s}$ was observed for the acetylcholinesterase reaction.

- Calculate V_{max} for this amount of enzyme.
- Calculate k_{cat} for acetylcholinesterase.
- Calculate the catalytic efficiency (k_{cat}/K_m) for acetylcholinesterase.
- Does acetylcholinesterase approach catalytic perfection?

- 16. Quantitative Relationships between Rate Constants to Calculate K_m , Kinetic Efficiency (k_{cat}/K_m) and V_{max} - VI** The enzyme catalase catalyzes the decomposition of hydrogen peroxide:

The turnover number (k_{cat}) for catalase is $40,000,000 \text{ s}^{-1}$. The K_m of catalase for its substrate H_2O_2 is 0.11 M.

- In an experiment using 3 nanomole/L of catalase, what is V_{max} ?
- What is v when $[\text{H}_2\text{O}_2] = 0.75 \text{ M}$?
- What is the catalytic efficiency of catalase?
- Does catalase approach catalytic perfection?

- 17. Calculate Catalytic Efficiency Using Lineweaver–Burk or Hanes–Woolf Plots** The enzymatic activity of two enzymes, A and B, was studied. The results for enzyme A (tested at 20 nM) are shown in a Lineweaver–Burk format, while the results for enzyme B (tested at 5 nM) are shown in a Hanes–Woolf format. Calculate the catalytic efficiency for each enzyme.

18. The Effect of the Accumulation of P, the Reaction Product, on the Michaelis–Menten Equation Equation 13.9 presents the simple Michaelis–Menten situation where the reaction is considered to be irreversible ($[P]$ is negligible). Many enzymatic reactions are reversible, and P does accumulate.

- Derive an equation for v , the rate of the enzyme-catalyzed reaction $S \rightarrow P$ in terms of a modified Michaelis–Menten model that incorporates the reverse reaction that will occur in the presence of product, P.
- Solve this modified Michaelis–Menten equation for the special situation when $v = 0$ (that is, $S \rightleftharpoons P$ is at equilibrium, or in other words, $K_{eq} = [P]/[S]$).

(J. B. S. Haldane first described this reversible Michaelis–Menten modification, and his expression for K_{eq} in terms of the modified M–M equation is known as the Haldane relationship.)

19. Michaelis–Menten Kinetics Enzyme A follows Simple Michaelis–Menten Kinetics.

- The K_m of enzyme A for its substrate S is $K_m^S = 1 \text{ mM}$. Enzyme A also acts on substrate T and its $K_m^T = 10 \text{ mM}$. Is S or T the preferred substrate for enzyme A?
- The rate constant k_2 with substrate S is $2 \times 10^4 \text{ s}^{-1}$; with substrate T, $k_2 = 4 \times 10^5 \text{ s}^{-1}$. Does enzyme A use substrate S or substrate T with greater catalytic efficiency?

20. The Chemical Properties of Lemon Juice When preparing fruit salad containing apple slices, lemon juice is sprinkled to prevent the darkening of the apple slices. The darkening is an enzymatic oxidation reaction (due to exposure to oxygen in air) catalyzed by polyphenol oxidase. Lemon juice contains about 75% carbohydrates, 10% organic acids, 5% amino acids, 3% inorganics, 2.5% vitamins, and 1% lipids. Using the information provided, how would you explain the action of lemon juice?

21. Enzymatic Activity in Clinical Analyses Clinical diagnostics often depend on the detection of enzymatic activity in a patient's blood sample. One example is the analysis of lactate dehydrogenase (LDH) activity in blood to diagnose a myocardial infarction. For the detection of the potential presence of an enzyme in a blood sample, substrate is added to the sample at concentrations a 100-times (or more) higher than the known value of K_m . Give an explanation for why such a high substrate concentration is used.

22. Enzymatic Perfection As discussed in section 13.3i, the rate of diffusion is a limiting factor for enzymatic activity. Diffusion rates increase with increasing temperature. However, increasing temperature does not necessarily increase enzymatic activity. Give an explanation.

Think-Pair-Share Question

The study of the kinetics of the degradation of a biopolymer (protein, nucleic acid, polysaccharide) is complicated, since the number of internal bonds that are broken per unit of time needs to be determined. This can be done by monitoring the decline in molecular mass as the biopolymer is gradually broken into smaller pieces. Consider the study of the degradation of 500 mg of four polysaccharides with different molecular masses. Results of the decline in molecular mass for each polysaccharide are listed in the table.

Reaction time (min)	Polysaccharide A mol mass (g/mol)	Polysaccharide B mol mass (g/mol)	Polysaccharide C mol mass (g/mol)	Polysaccharide D mol mass (g/mol)
0	250,000	400,000	1,000,000	100,000
5	97,561	80,000	117,647	66,667
10	60,606	44,444	62,500	50,000
15	43,956	30,769	42,533	40,000

Pick two polysaccharides (another student can pick the remaining two polysaccharides).

- Plot the molecular mass as a function of the reaction time.
- Determine the velocity of the reaction as the moles of glycosidic bonds broken per minute.
- Plot the reciprocal values of the molecular mass as a function of the reaction time. Correlate the slopes of the lines with the results from (b). What is the significance of your observation?

23. Enzyme Activity Profiles Use Figure 13.12 to Answer the Following Questions.

- Is the enzyme whose temperature versus activity profile is shown in Figure 13.12 likely to be from an animal or a plant? Why?
- What do you think the temperature versus activity profile for an enzyme from a thermophilic prokaryote growing in an 80°C pool of water would resemble?

Mechanisms of Enzyme Action

14

David W. Gristham

◀ Like the workings of a watch, the details of enzyme mechanisms are at once complex and simple.

*No single thing abides but all things flow.
Fragment to fragment clings and thus they grow
Until we know them by name.
Then by degrees they change and are no more the
things we know.*

Lucretius (ca. 94 B.C.–50 B.C.)

Essential Question

Enzymes derive their catalytic prowess from the simple chemistry of breaking and making bonds. This chapter will explore the unique features of this chemistry. The mechanisms of thousands of enzymes have been studied in at least some detail. In this chapter, it will be possible to examine only a few of these. **What are the universal chemical principles that influence the mechanisms of enzymes and underlie their enormous catalytic power?**

All living things depend on enzymes. These remarkable catalysts enable metabolic reactions to proceed at rates that sustain life. They are essential for respiration, digesting food, muscle and nerve function, and thousands of other roles. This chapter describes the chemical foundations of enzyme function.

14.1 What Are the Magnitudes of Enzyme-Induced Rate Accelerations?

Enzymes are powerful catalysts. Enzyme-catalyzed reactions are typically 10^7 to 10^{15} times faster than their uncatalyzed counterparts (Table 14.1). The most impressive reaction acceleration known (2×10^{26} over the uncatalyzed rate) is that of the alkyl-sulfatase from the soil bacterium *Corynebacterium Bla*.

These large rate accelerations correspond to substantial decreases in the free energy of activation for the reaction in question. For example, urea is hydrolyzed by *urease*:

The catalyzed reaction shows an energy of activation 84 kJ/mol smaller than that for the corresponding uncatalyzed reaction. To fully understand any enzyme reaction, it is important to account for the rate acceleration in terms of the structure of the enzyme and its mechanism of action.

Key Questions

- 14.1 What Are the Magnitudes of Enzyme-Induced Rate Accelerations?
- 14.2 What Role Does Transition-State Stabilization Play in Enzyme Catalysis?
- 14.3 How Does Destabilization of ES Affect Enzyme Catalysis?
- 14.4 What Are Transition State Analogs and How Tightly Do They Bind to the Active Sites of Enzymes?
- 14.5 What Are the Mechanisms of Enzyme Catalysis?
- 14.6 What Can Be Learned from the Mechanisms of Some Typical Enzymes?

Table 14.1 A Comparison of Enzyme-Catalyzed Reactions and Their Uncatalyzed Counterparts

Reaction	Enzyme	Uncatalyzed Rate, v_u (sec ⁻¹)	Catalyzed Rate, v_e (sec ⁻¹)	v_e/v_u
$R-O-SO_3^- + H_2O \longrightarrow R-OH + SO_4^{2-} + H^+$	Alkylsulfatase (S—O cleavage)	3×10^{-26}	6.9	$\sim 2 \times 10^{26}$
Fructose-1,6-bisP $\longrightarrow$ fructose-6-P + P_i	Fructose-1,6-bisphosphatase	2×10^{-20}	21	1.05×10^{21}
$(\text{Glucose})_n + H_2O \longrightarrow (\text{glucose})_{n-2} + \text{maltose}$	β -amylase	1.9×10^{-15}	1.4×10^3	7.2×10^{17}
DNA, RNA cleavage	Staphylococcal nuclease	7×10^{-16}	95	1.4×10^{17}
$CH_3-O-PO_3^{2-} + H_2O \longrightarrow CH_3OH + HPO_4^{2-}$	Alkaline phosphatase	1×10^{-15}	14	1.4×10^{16}
$H_2N-\overset{\overset{O}{\parallel}}{C}-NH_2 + 2 H_2O + H^+ \longrightarrow 2 NH_4^+ + HCO_3^-$	Urease	3×10^{-10}	3×10^4	1×10^{14}
$R-\overset{\overset{O}{\parallel}}{C}-O-CH_2CH_3 + H_2O \longrightarrow RCOOH + HOCH_2CH_3$	Chymotrypsin	1×10^{-10}	1×10^2	1×10^{12}
Glucose + ATP $\longrightarrow$ Glucose-6-P + ADP	Hexokinase	$<1 \times 10^{-13}$	1.3×10^{-3}	$>1.3 \times 10^{10}$
$CH_3CH_2OH + NAD^+ \longrightarrow CH_3\overset{\overset{O}{\parallel}}{C}H + NADH + H^+$	Alcohol dehydrogenase	$<6 \times 10^{-12}$	2.7×10^{-5}	$>4.5 \times 10^6$
$CO_2 + H_2O \longrightarrow HCO_3^- + H^+$	Carbonic anhydrase	10^{-2}	10^5	1×10^7
Creatine + ATP $\longrightarrow$ Cr-P + ADP	Creatine kinase	$<3 \times 10^{-9}$	4×10^{-5}	$>1.33 \times 10^4$

Catalytic proficiency: the extreme case of S—O cleaving sulfatases. *Journal of the American Chemical Society* 134:525–531.

In all chemical reactions, the reacting atoms or molecules pass through a state that is intermediate in structure between the reactant(s) and the product(s). Consider the transfer of a proton from a water molecule to a chloride anion:

In the middle structure, the proton undergoing transfer is shared equally by the hydroxyl and chloride anions. This structure represents, as nearly as possible, the transition between the reactants and products, and it is known as the **transition state**.¹ All transition states contain at least one partially formed bond.

Linus Pauling was the first to suggest (in 1946) that the active sites of enzymes bind the transition state more readily than the substrate and that, by doing so, they stabilize the transition state and lower the activation energy of the reaction. Many subsequent studies have shown that this idea is essentially correct, but it is just the beginning in understanding what enzymes do. Reaction rates can also be accelerated by destabilizing (raising the energy of) the enzyme–substrate complex. Chemical groups arrayed across the active site actually guide the entering substrate toward the formation of the transition state. Thus, the enzyme active site is said to be preorganized. Enzymes are dynamic, and fluctuations in the active-site structure are presumed to organize the initial enzyme–substrate complex into a reactive conformation and on to the transition state. Along the way, electrostatic and hydrophobic interactions between the enzyme and the substrate mediate and direct these changes that make the reaction possible. Often, catalytic groups provided by the enzyme participate directly in proton transfers and other bond-making and bond-breaking events.

This chapter describes and elaborates on each of these contributions to the catalytic prowess of enzymes and then illustrates the lessons learned by looking closely at the mechanisms of three well-understood enzymes.

¹It is important to distinguish **transition states** from **intermediates**. A transition state is envisioned as an extreme distortion of a bond, and thus the lifetime of a typical transition state is viewed as being on the order of the lifetime of a bond vibration, typically 10^{-13} sec. Intermediates, on the other hand, are longer lived, with lifetimes in the range of 10^{-13} to 10^{-3} sec.

14.2 What Role Does Transition-State Stabilization Play in Enzyme Catalysis?

Chemical reactions in which a substrate (S) is converted to a product (P) can be pictured as involving a transition state (which we henceforth denote as $X^\ddagger$), a species intermediate in structure between S and P (Figure 14.1). As seen in Chapter 13, the catalytic role of an enzyme is to reduce the energy barrier between substrate and transition state. This is accomplished through the formation of an **enzyme–substrate complex** (ES). This complex is converted to product by passing through a transition state, $EX^\ddagger$ (Figure 14.1). As shown, the energy of $EX^\ddagger$ is clearly lower than that of $X^\ddagger$. One might be tempted to conclude that this decrease in energy explains the rate enhancement achieved by the enzyme, but there is more to the story.

The energy barrier for the uncatalyzed reaction (Figure 14.1) is, of course, the difference in energies of the S and $X^\ddagger$ states. Similarly, the energy barrier to be surmounted in the enzyme-catalyzed reaction, assuming that E is saturated with S, is the energy difference between ES and $EX^\ddagger$. *Reaction rate acceleration by an enzyme means simply that the energy barrier between ES and $EX^\ddagger$ is less than the energy barrier between S and $X^\ddagger$.* In terms of the free energies of activation for the enzyme-catalyzed (e) and uncatalyzed (u) reactions, $\Delta G_e^\ddagger < \Delta G_u^\ddagger$.

There are important consequences for this statement. The enzyme must stabilize the transition-state complex, $EX^\ddagger$, more than it stabilizes the substrate complex, ES. Put another way, enzymes bind the transition-state structure more tightly than the substrate (or the product). The dissociation constant for the enzyme–substrate complex is

$$K_S = \frac{[E][S]}{[ES]} \quad (14.1)$$

and the corresponding dissociation constant for the transition-state complex is

$$K_T = \frac{[E][X^\ddagger]}{[EX^\ddagger]} \quad (14.2)$$

Enzyme catalysis requires that $K_T < K_S$. According to **transition-state theory**, the rate constants for the enzyme-catalyzed (k_e) and uncatalyzed (k_u) reactions can be related to K_S and K_T by

$$k_e/k_u \leq K_S/K_T \quad (14.3)$$

Thus, the enzymatic rate enhancement is approximately equal to the ratio of the dissociation constants of the enzyme–substrate and enzyme–transition-state complexes, at least when E is saturated with S.

Figure 14.1 Enzymes catalyze reactions by lowering the activation energy. Here the free energy of activation for (a) the uncatalyzed reaction, $\Delta G_u^\ddagger$, is larger than that for (b) the enzyme-catalyzed reaction, $\Delta G_e^\ddagger$.

Figure 14.2 The intrinsic binding energy of the enzyme–substrate (ES) complex (ΔG_b) is compensated to some extent by entropy loss due to the binding of E and S ($T\Delta S$) and by destabilization of ES (ΔG_d) by strain, distortion, desolvation, and similar effects. If ΔG_b were not compensated by $T\Delta S$ and ΔG_d , the formation of ES would follow the dashed line.

14.3 How Does Destabilization of the Enzyme-Substrate Complex Affect Enzyme Catalysis?

How is it that the transition state $X^\ddagger$ is stabilized more than S at the enzyme active site? To understand this, consider the formation of the enzyme-substrate complex, ES. There are a number of important contributions to the free energy difference between the uncomplexed enzyme and substrate (E + S) and the ES complex (Figure 14.2). The favorable interactions between the substrate and amino acid residues on the enzyme account for the **intrinsic binding energy**, ΔG_b . The intrinsic binding energy ensures the favorable formation of the ES complex, but if uncompensated, it makes the activation energy for the enzyme-catalyzed reaction unnecessarily large and wastes some of the catalytic power of the enzyme. G_b is partially compensated by entropy loss due to the binding of E and S ($T\Delta S$) and by destabilization of ES (G_d) by strain, distortion, desolvation, and similar effects.

Compare the two cases in Figure 14.3. If the binding of the substrate is too tight (part a), there is no catalysis. On the other hand, if the ES complex is raised in energy (part b), catalysis can occur. Because the enzymatic reaction rate is determined by the difference in energies between ES and $EX^\ddagger$, the smaller this difference, the faster the enzyme-catalyzed reaction. Tight binding of the substrate deepens the energy well of the ES complex and actually lowers the rate of the reaction.

The message of Figure 14.3 is that raising the energy of ES will increase the enzyme-catalyzed reaction rate. As shown in this figure, this is accomplished in two ways: (1) **loss of entropy** due to the binding of S to E and (2) **destabilization of ES** by strain, distortion, desolvation, or other similar effects. The entropy loss arises from the formation of the ES complex (Figure 14.4), a highly organized (low-entropy) entity compared with E + S in solution (a disordered, high-entropy situation). Because ΔS is negative for this process, the term $-T\Delta S$ is a positive quantity, and *the intrinsic binding energy of ES is compensated to some extent by the entropy loss that attends the formation of the complex.*

Destabilization of the ES complex can involve *structural strain*, *desolvation*, or *electrostatic effects*. Destabilization by strain or distortion is usually just a consequence of the fact (noted previously) that *the enzyme is designed to bind the transition state more strongly than the substrate*. When the substrate binds, the imperfect nature of the “fit” results in distortion or strain in the substrate, the enzyme, or both.

Solvation of charged groups on a substrate in solution releases energy, making the charged substrate more stable. When a substrate with charged groups moves from water into an enzyme active site (Figure 14.4), the charged groups are often desolvated to some extent, becoming less stable and therefore more reactive.

Similarly, when a substrate enters the active site, charged groups may be forced to interact (unfavorably) with charges of like sign, resulting in *electrostatic destabilization*

Figure 14.3 Increasing the energy of the ES complex raises the enzyme-catalyzed reaction rate. **(a)** Catalysis does not occur if the ES complex and the transition state for the reaction are stabilized to equal extents. **(b)** Catalysis *will* occur if the transition state is stabilized to a greater extent than the ES complex (*right*). Entropy loss and destabilization of the ES complex ΔG_d ensure that this will be the case.

Figure 14.4 Interactions that can destabilize the ES complex, increasing the rate of the enzyme-catalyzed reaction. **(a)** Formation of the ES complex results in entropy loss. Before binding, E and S are free to undergo translational and rotational motion. The ES complex is a more highly ordered, low-entropy complex. **(b)** Substrates typically lose waters of hydration in the formation of the ES complex. Desolvation raises the energy of the ES complex, making it more reactive. **(c)** Electrostatic destabilization of a substrate may arise from juxtaposition of like charges in the active site. If such charge repulsion is relieved in the course of the reaction, electrostatic destabilization can result in a rate increase.

(Figure 14.4). The reaction pathway acts in part to remove this stress. If the charge on the substrate is diminished or lost in the course of reaction, electrostatic destabilization can result in rate acceleration.

Whether by strain, desolvation, or electrostatic effects, destabilization raises the energy of the ES complex, and this increase is summed in the term ΔG_d , the free energy of destabilization (see Figures 14.2 and 14.3).

14.4 What Are Transition State Analogs and How Tightly Do They Bind to the Active Sites of Enzymes?

How much more tightly does the transition state bind to an enzyme compared to substrates, products, and inhibitor molecules? To answer this important question, consider the magnitudes of K_S and K_T and the values of k_e and k_u in Equation 14.3. The ratio k_e/k_u may exceed 10^{16} , as noted previously. Given a ratio of 10^{16} and a typical K_S of $10^{-4} M$, the value of K_T would be $10^{-20} M$. The value of K_T for fructose-1,6-bisphosphatase is an astounding $7 \times 10^{-26} M$! This is the dissociation constant for the transition state from the enzyme, and this very low value corresponds to very tight binding of the transition state by the enzyme.

A Deeper Look

Transition-State Analogs Make Our World Better

Enzymes (human, plant, and bacterial) are often targets for drugs and other beneficial agents. Transition-state analogs (TSAs), with very high affinities for their enzyme-binding sites, often make ideal enzyme inhibitors, and TSAs have become ubiquitous therapeutic

agents that improve the lives of millions and millions of people. A few applications of transition-state analogs for human health and for agriculture are shown here.

Enalapril and Aliskiren Lower Blood Pressure

High blood pressure is a significant risk factor for cardiovascular disease, and drugs that lower blood pressure reduce the risk of heart attacks, heart failure, strokes, and kidney disease. Blood pressure is partly regulated by aldosterone, a steroid synthesized in the adrenal cortex and released in response to angiotensin II, a peptide produced from angiotensinogen in two proteolytic steps by renin (an aspartic protease) and angiotensin-converting enzyme (ACE). Vasotec (enalapril) manufactured by Merck and Biovail is an ACE inhibitor. Novartis and Speedel have developed Tekturna (aliskiren) as a renin inhibitor. Both are TSAs.

Enalapril

Aliskiren

Atorvastatin (Lipitor)

AP Images/Amy Sancetta

Statins Lower Serum Cholesterol

Statins such as Lipitor are powerful cholesterol-lowering drugs, because they are transition-state analog inhibitors of HMG-CoA reductase, a key enzyme in the biosynthetic pathway for cholesterol (discussed in Section 24.4).

Protease Inhibitors Are AIDS Drugs

Crixivan (indinavir) by Merck, Invirase (saquinavir) by Roche, and similar protease inhibitor drugs are transition-state analogs for the HIV-1 protease, discussed in Section 14.6.

Saquinavir

Tamiflu Is a Viral Neuraminidase Inhibitor

Influenza is a serious respiratory illness that affects 5% to 15% of the earth's population each year and results in 250,000 to 500,000 deaths annually, mostly among children and the elderly. Protection from influenza by vaccines is limited by the antigenic variation of the influenza virus. Neuraminidase, a major glycoprotein on the influenza virus membrane envelope, is essential for viral replication and infectivity. Tamiflu is a neuraminidase inhibitor and antiviral agent that mimics the transition state of the neuraminidase reaction.

Tamiflu

Juvenile Hormone Esterase Is a Pesticide Target

Insects have significant effects on human health, being the transmitting agents (vectors) for diseases such as malaria, West Nile virus, and viral encephalitis, all carried by mosquitoes, and Lyme disease and Rocky Mountain spotted fever, carried by ticks. One strategy for controlling insect populations is to alter the actions of **juvenile hormone**, a terpene-based substance that regulates insect life cycle processes. Levels of juvenile hormone are controlled by **juvenile hormone esterase (JHE)**, and inhibition of JHE is toxic to insects. OTFP (figure) is a potent transition-state analog inhibitor of JHE.

3-Octylthio-1,1,1-trifluoropropan-2-one (OTFP)

The 1918 flu pandemic killed more than 20 million people worldwide.

How Many Other Drug Targets Might There Be?

If the human genome contains approximately 20,500 genes, how many of these might be targets for drug therapy? Andrew Hopkins has proposed the term “druggable genome” to conceptualize the subset of human genes that might express proteins able to bind druglike molecules. The DrugBank database at <http://drugbank.com> contains more than 20,000 Food and Drug Administration (FDA) approved prescription drugs. Nearly half of these are directed specifically to enzymes. More than 18,000 experimental drugs are presently under study and testing. It is easy to imagine that thousands more drugs will eventually be developed, with many of these designed as transition-state analogs for enzyme reactions.

It is unlikely that such tight binding in an enzyme transition state will ever be determined in a direct equilibrium measurement, however, because the transition state itself is a moving target. It exists only for about 10^{-14} to 10^{-13} sec, less than the time required for a bond vibration. On the other hand, the nature of the elusive transition state can be explored using **transition-state analogs**, stable molecules that are chemically and structurally similar to the transition state. Such molecules should bind more strongly than a substrate and more strongly than competitive inhibitors that bear no significant similarity to the transition state. Hundreds of examples of such behavior have been reported. For example, Robert Abeles

studied a series of inhibitors of **proline racemase** (Figure 14.5) and found that pyrrole-2-carboxylate bound to the enzyme 160 times more tightly than L-proline, the normal substrate. This analog binds so tightly because it is planar and is similar in structure to the planar transition state for the racemization of proline. Two other examples of transition-state analogs are shown in Figure 14.6. Phosphoglycolohydroxamate binds 40,000 times

Proline racemase reaction

Figure 14.5 The proline racemase reaction interconverts the L- and D-isomers of proline. (Pink highlights show the two configurations of proline.) Pyrrole-2-carboxylate and Δ-1-pyrroline-2-carboxylate mimic the planar transition state of the reaction.

(a) Yeast aldolase reaction

(b) Calf intestinal adenosine deaminase reaction

Figure 14.6 Examples of transition state analogs. (a) Phosphoglycolohydroxamate is an analog of the enediolate transition state of the yeast aldolase reaction. (b) Purine riboside, a potent inhibitor of the calf intestinal adenosine deaminase reaction, binds to adenosine deaminase as the 1,6-hydrate. The hydrated form of purine riboside is an analog of the proposed transition state for the reaction.

Chemistry in History

Dr. John Cornforth

John Cornforth (1918–2013) earned a B.S. in organic chemistry at the University of Sydney in Sydney, Australia. The next year, he and another organic chemist from Sydney, Rita Harradence, won prestigious scholarships to study abroad. Both chose to go to Oxford to do their doctoral work with Sir Robert Robinson, studying cholesterol biosynthesis. As World War II unfolded, Robinson's lab turned to study of methods for preparing penicillin and Robinson assigned Cornforth and Harradence to work together on the synthesis of penicillamine, to aid the Allies. Cornforth and Harradence married while still in graduate school and continued their collaboration, authoring 41 papers together over their careers.

Dr. Cornforth suffered from otosclerosis which led to progressive hearing loss that left him completely deaf in his early 20s. He attributed his pursuit of chemistry as a career to a talented teacher at his high school and the impression that his impending deafness would not be much of a hindrance in the field. Cornforth received the 1975 Nobel Prize in Chemistry for his studies of the stereochemistry of the enzymes involved in cholesterol biosynthesis. In his Nobel biography, Cornforth said of his wife Rita: “she has eased for me beyond measure the difficulties of communication that accompany deafness; her encouragement and fortitude have been my strongest supports.”

more tightly to yeast aldolase than the substrate dihydroxyacetone phosphate. Even more remarkable, the 1,6-hydrate of purine ribonucleoside has been estimated to bind to adenosine deaminase with a K_i of $3 \times 10^{-13} M$!

It should be noted that transition-state analogs are only approximations of the transition state itself and will never bind as tightly as would be expected for the true transition state. These analogs are, after all, stable molecules and cannot be expected to resemble a true transition state too closely.

14.5 | What Are the Mechanisms of Enzyme Catalysis?

Enzymes employ a variety of chemical strategies to catalyze reactions. This section describes those found most often in enzymes – near-attack conformations, protein dynamics, covalent catalysis, general acid-base catalysis, low-barrier hydrogen bonds, quantum mechanical tunneling, and metal-ion catalysis.

14.5a Enzymes Facilitate Formation of Near-Attack Conformations

Exquisite and beautiful details of enzyme active-site structure and dynamics have emerged from X-ray crystal structures of enzymes and computer simulations of molecular conformation and motion at the active site. Importantly, these studies have shown that the reacting atoms and catalytic groups are precisely positioned for their roles. This preorganization of the active site allows it to select and stabilize conformations of the substrate(s) in which *the reacting atoms are in van der Waals contact and at an angle resembling the bond to be formed in the transition state*. Thomas Bruice has termed such arrangements **near-attack conformations (NACs)**, and he has proposed that NACs are the precursors to transition states of reactions (Figure 14.7). In the absence of an enzyme, potential reactant molecules adopt a NAC only about 0.0001% of the time. On the other hand, NACs have been shown to form in enzyme active sites from 1% to 70% of the time.

The *alcohol dehydrogenase (ADH)* reaction provides a good example of a NAC on the pathway to the reaction transition state (Figure 14.8). The ADH reaction converts a primary alcohol to an aldehyde (through an ordered, single-displacement mechanism; see Section 13.5). The reaction proceeds by a proton transfer to water followed by a hydride transfer to NAD^+ . In the enzyme active site, Ser^{48} accepts the proton from the alcohol substrate, the resulting negative charge is stabilized by a zinc ion, and the substrate *pro-R* hydrogen is poised above the NAD^1 ring prior to hydride transfer (Figure 14.8). Computer simulations of the enzyme-substrate complex involving the deprotonated alcohol show that this intermediate exists as a NAC 60% of the time. The kinetic advantage of such an enzymatic reaction, compared with its nonezymatic counterpart, is the *ease of formation of the NAC and the favorable free energy difference between the NAC and the transition state* (see Figure 14.7).

Figure 14.7 Reacting atoms and catalytic groups must be precisely positioned to form near-attack conformations (NACs). **(a)** For reactions involving bonding between O, N, C, and S atoms, NACs are characterized as having reacting atoms within 3.2 Å and an approach angle of $\pm 15^\circ$ of the bonding angle in the transition state. **(b)** In an enzyme active site, the enzyme-substrate complex and the NAC are separated by a small energy barrier, and NACs form readily. In the absence of the enzyme, the energy gap between the substrate and the NAC is much greater and NACs are rarely formed. The energy separation between the NAC and the transition state is approximately the same in the presence and absence of the enzyme. (Adapted from Bruice, T., 2002. A view at the millennium: the efficiency of enzymatic catalysis. *Accounts of Chemical Research* 35:139–148.)

A Deeper Look

How to Read and Write Mechanisms

The custom among chemists and biochemists of writing chemical reaction mechanisms with electron dots and curved arrows began with two of the greatest chemists of the twentieth century. Gilbert Newton Lewis was the first to suggest that a covalent bond consists of a shared pair of electrons, and Sir Robert Robinson was the first to use curved arrows to illustrate a mechanism in a paper in the *Journal of the Chemical Society* in 1922.

Learning to read and write reaction mechanisms should begin with a review of Lewis dot structures in any good introductory chemistry text. It is also important to understand valence electrons and formal charge. The formal charge of an atom is calculated as the number of valence electrons minus the electrons owned by an atom. More properly

$$\text{Formal charge} = \text{group number} - \text{nonbonding electrons} - (1/2 \text{ shared electrons})$$

Students of mechanisms should also appreciate electronegativity—the tendency of an atom to attract electrons. Electronegativities of the atoms important in biochemistry go in the order

Thus, in a C–N bond, the N should be viewed as more electron rich and C as electron deficient. An electron-rich atom is termed *nucleophilic* and will have a tendency to react with an electron-deficient (electrophilic) atom.

In written mechanisms, a curved arrow shows the movement of an electron pair from its original position to a new one. The tail of the arrow shows where the electron pair comes from, and the head of the arrow shows where the electron pair is going. Thus, the arrow represents the actual movement of a pair of electrons from a filled orbital into an empty one. By convention, an arrow with a full arrowhead $\curvearrowright$ represents movement of an electron pair, whereas a half arrowhead $\frown$ represents a single electron (for example, in a free radical reaction). For a bond-breaking event, the arrow begins in the middle of the bond, and the arrowhead points at the atom that will accept the electrons:

For a bond-making event, the arrow begins at the source of the electrons (for example, a nonbonded pair), and the arrowhead points to the atom where the new bond will be formed:

It has been estimated that 75% of the steps in enzyme reaction mechanisms are proton (H^+) transfers. If the proton is donated or accepted by a group on the enzyme, it is often convenient (and traditional) to represent that group as B, for base, even if B is protonated and behaving as an acid:

It is important to appreciate that a proton transfer can change a nucleophile into an electrophile, and vice versa. Thus, it is necessary to consider (1) the protonation states of substrate and active-site residues and (2) how pK_a values can change in the environment of the active site. For example, an active-site histidine, which might normally be protonated, can be deprotonated by another group and then act as a base, accepting a proton from the substrate:

Water can often act as an acid or base at the active site through proton transfer with an assisting active-site residue:

These concepts provide a sense of what is reasonable and what makes good chemical logic in a reaction.

14.5b Protein Motions Are Essential to Enzyme Catalysis

Proteins are constantly moving. As noted in Chapter 6 (Table 6.2), bonds vibrate, side chains bend and rotate, backbone loops wiggle and sway, and whole domains move with respect to each other. Enzymes depend on such motions to initiate and direct catalytic events. Protein motions may support catalysis in several ways: Active site conformation changes can

- Assist substrate binding
- Bring catalytic groups into position around a substrate
- Induce formation of a NAC

Figure 14.8 The complex of horse liver ADH with benzyl alcohol illustrates the approach to a near-attack conformation. Computer simulations by Bruice and co-workers show that the side-chain oxygen of Ser⁴⁸ approaches within 1.8 Å of the hydroxyl hydrogen of the substrate, benzyl alcohol, and that the *pro-R* hydrogen of benzyl alcohol lies 2.75 Å from the C-4 carbon of the nicotinamide ring. The reaction mechanism involves hydroxyl proton abstraction by Ser⁴⁸ and hydride transfer from the substrate to C-4 of the NAD⁺ nicotinamide ring (PDB id = 1HLD).

Figure 14.9 Human cyclophilin A is a *prolyl isomerase*. **(a)** This enzyme catalyzes the interconversion of *trans* and *cis* conformations of proline in peptides. **(b)** The active site of cyclophilin with a bound peptide containing proline in *trans* (left) and *cis* (right) conformations (PDB id = 1RMH).

- Assist in bond making and bond breaking
- Facilitate conversion of substrate to product

A good example of protein motions facilitating catalysis is human *cyclophilin A*, which catalyzes the interconversion between *cis* and *trans* conformations of proline in peptides (Figure 14.9). NMR studies of cyclophilin A have provided direct measurements of the active-site motions occurring in this enzyme. Certain active-site residues (Lys⁸², Leu⁹⁸, Ser⁹⁹, Ala¹⁰¹, Gln¹⁰², Ala¹⁰³, and Gly¹⁰⁹) of the enzyme undergo conformation changes during substrate binding, whereas Arg³⁵ is involved directly in the *cis*-to-*trans* interconversion itself. The residues undergoing motion during catalysis are shown in Figure 14.10.

The protein motions that assist catalysis may be quite complex. Stephen Benkovic and Sharon Hammes-Schiffer have characterized an extensive network of coupled protein motions in dihydrofolate reductase. This network extends from the active site to the surface of the protein, and the motions in this network span time scales of femtoseconds (10^{-15} sec)

Figure 14.10 Catalysis in enzyme active sites depends on motion of active-site residues. NMR studies by Dorothee Kern and her co-workers show that several cyclophilin active-site residues, including Arg⁵⁵ (red dot) and Lys⁸², Leu⁹⁸, Ser⁹⁹, Ala¹⁰¹, Gln¹⁰², Ala¹⁰³, and Gly¹⁰⁹ (green dots), undergo greater motion during catalysis than residues elsewhere in the protein. (Adapted from Eisenmesser, E., et al., 2002. Enzyme dynamics during catalysis. *Science* 295:1520–1523.)

to milliseconds. Such extensive networks of motion make it likely that the entire folded structure of the protein may be involved in catalysis at the active site.

14.5c Covalent Catalysis

Some enzyme reactions derive much of their rate acceleration from the formation of *covalent bonds* between enzyme and substrate. Consider the reaction:

and an enzymatic version of this reaction involving formation of a **covalent intermediate**:

If the enzyme-catalyzed reaction is to be faster than the uncatalyzed case, the acceptor group on the enzyme must be a better attacking group than Y and a better leaving group than X. Note that most enzymes that carry out covalent catalysis have ping-pong kinetic mechanisms.

The side chains of amino acids in proteins offer a variety of **nucleophilic centers** for catalysis, including amines, carboxylates, aryl and alkyl hydroxyls, imidazoles, and thiol groups. These groups readily attack electrophilic centers of substrates, forming covalently bonded enzyme-substrate intermediates. Typical electrophilic centers in substrates include phosphoryl groups, acyl groups, and glycosyl groups (Figure 14.11). The

Figure 14.11 Examples of covalent bond formation between enzyme and substrate. In each case, a nucleophilic center (X:) on an enzyme attacks an electrophilic center on a substrate.

Table 14.2 Enzymes That Form Covalent Intermediates

Enzyme	Reacting Group	Covalent Intermediate
Trypsin Chymotrypsin (Section 14.6)	Serine	Acyl-Ser
Glyceraldehyde-3-P dehydrogenase (Section 18.4)	Cysteine	Acyl-Cys
Phosphoglucomutase (Section 15.5)	Serine	Phospho-Ser
Phosphoglycerate mutase (Section 18.4) Succinyl-CoA synthetase (Section 19.4)	Histidine	Phospho-His
Aldolase (Section 18.3) Pyridoxal phosphate enzymes (Sections 13.5, 25.4, and 25.5)	Lysine and other amino groups	Schiff base

covalent intermediates thus formed can be attacked in a subsequent step by a water molecule or a second substrate, giving the desired product. **Covalent electrophilic catalysis** is also observed, but it usually involves coenzyme adducts that generate electrophilic centers. Hundreds of enzymes are now known to form covalent intermediates during catalysis. Several examples of covalent catalysis will be discussed in detail in later chapters, as noted in Table 14.2.

14.5d General Acid-Base Catalysis

Nearly all enzyme reactions involve some degree of acid or base catalysis. There are two types of acid-base catalysis: (1) **specific acid-base catalysis**, in which the reaction is accelerated by H^+ or OH^- diffusing in from the solution, and (2) **general acid-base catalysis**, in which H^+ or OH^- is created in the transition state by another molecule or group, which is termed the general acid or general base, respectively. *By definition, general acid-base catalysis is catalysis in which a proton is transferred in the transition state.* Consider the hydrolysis of *p*-nitrophenylacetate by specific base catalysis or by general base catalysis, with imidazole acting as a general base (Figure 14.12). In the

Reaction

Specific base mechanism

Figure 14.12 Catalysis of *p*-nitrophenylacetate hydrolysis can occur either by specific base hydrolysis (where hydroxide from the solution is the attacking nucleophile) or by general base catalysis (in which a base like imidazole can promote hydroxide attack on the substrate carbonyl carbon by removing a proton from a nearby water molecule).

specific base mechanism, hydroxide diffuses into the reaction from solution. In the general base mechanism, the hydroxide that catalyzes the reaction is generated from water in the transition state. The water has been made more nucleophilic without generation of a high concentration of OH^- or without the formation of unstable, high-energy species. General acid or general base catalysis may increase reaction rates 10- to 100-fold. In an enzyme, ionizable groups on the protein provide the H^+ transferred in the transition state. An ionizable group will be most effective as an H^+ transferring agent at or near its $\text{p}K_a$. Because the $\text{p}K_a$ of the histidine side chain is near 7, histidine is often the most effective general acid or base.

14.5e Low-Barrier Hydrogen Bonds

Low-barrier hydrogen bonds contribute to catalysis in some enzyme reactions. As previously noted, the typical strength of a hydrogen bond is 10 to 30 kJ/mol. For an $\text{O}-\text{H}\cdots\text{O}$ hydrogen bond, the $\text{O}-\text{O}$ separation is typically 0.28 nm and the H bond is a relatively weak electrostatic interaction. The hydrogen is firmly linked to one of the oxygens at a distance of approximately 0.1 nm, and the distance to the other oxygen is thus about 0.18 nm, which corresponds to a bond order of about 0.07. (**Bond order** refers to the number of electron pairs in a bond. For a single bond, the bond order is 1.) Not all hydrogen bonds are weak, however. As the distance between heteroatoms becomes smaller, the overall bond becomes stronger, the hydrogen becomes centered, and the bond order approaches 0.5 for both $\text{O}-\text{H}$ interactions (Figure 14.13). These interactions are more nearly covalent in nature, and the stabilization energy is much higher. Notably, the barrier that the hydrogen atom must surmount to exchange oxygens becomes lower as the $\text{O}-\text{O}$ separation decreases (Figure 14.13). When the barrier-to-hydrogen exchange has dropped to the point that it is at or below the zero-point energy level of hydrogen, the interaction is referred to as a **low-barrier hydrogen bond (LBHB)**. The hydrogen is now free to move anywhere between the two oxygens (or, more generally, two heteroatoms). The stabilization energy of LBHBs may approach 100 kJ/mol in the gas phase and 60 kJ/mol or more in solution. LBHBs require matched $\text{p}K_a$ s for the two electronegative atoms that share the hydrogen. As the two $\text{p}K_a$ values diverge, the stabilization energy of the LBHB is decreased. Widely divergent $\text{p}K_a$ values thus correspond to ordinary, weak hydrogen bonds.

How may low-barrier hydrogen bonds affect enzyme catalysis? A weak hydrogen bond in an enzyme ground state may become an LBHB in a transient intermediate, or even in the transition state for the reaction. In such a case, the energy released in forming the LBHB is used to help the reaction that forms it, lowering the activation barrier for the reaction. Alternatively, the purpose of the LBHB may be to redistribute electron

Figure 14.13 Comparison of (a) conventional (weak) hydrogen bonds and (b, c) low-barrier hydrogen bonds (b and c). The horizontal line in each case is the zero-point energy of hydrogen. (a) An $\text{O}-\text{H}-\text{O}$ hydrogen bond of length 0.28 nm, with the hydrogen attached to one or the other of the oxygens. The bond order for the stronger $\text{O}-\text{H}$ interaction is approximately 1.0, and the weaker $\text{O}-\text{H}$ interaction is 0.07. As the $\text{O}-\text{O}$ distance decreases, the hydrogen bond becomes stronger, and the bond order of the weakest interaction increases. In (b), the $\text{O}-\text{O}$ distance is 0.25 nm, and the barrier is equal to the zero-point energy. In (c), the $\text{O}-\text{O}$ distance is 0.23 to 0.24 nm, and the bond order of each $\text{O}-\text{H}$ interaction is 0.5. (d) If the distance for particle (proton or electron) transfer is sufficiently small, the overlap of probability functions (red curves) permits efficient quantum mechanical tunneling between donor (D) and acceptor (A) groups.

density in the reactive intermediate, achieving rate acceleration by facilitation of hydrogen tunneling. Enzyme mechanisms that will be examined in the next section and also later in this chapter (the serine proteases and aspartic proteases) appear to depend upon one or the other of these effects.

14.5f Quantum Mechanical Tunneling in Electron and Proton Transfers

The fundamental premise of transition-state theory, as described in this chapter, is that reactants cannot become products until they acquire enough energy to distort their structures to that of the transition state. However, **quantum mechanical tunneling** offers a path around this energy barrier, and many enzymes exploit it. According to quantum theory, if an atom or electron is transferred in a chemical reaction from one site to another across an activation barrier, there is a finite probability that the particle will appear (as part of the product) on the other side of the energy barrier, even though it cannot achieve sufficient energy to reach the transition state. The likelihood of tunneling depends on the distance over which the particle must move and the shape (width and height) of the

Human Biochemistry

Antibiotic Resistance by Superbugs

Penicillin (Figure 13.18), the first antibiotic drug, became widely available in the 1940s, but treating bacterial infections with penicillin and other antibiotics precipitated the emergence of antibiotic-resistant bacteria. Over the last 70 years, whenever a new antibiotic has been introduced, resistant strains of bacteria have appeared quickly—a history that evokes images of war. Whenever challenged by a new antibiotic, bacteria fight back with the powerful weapon of spontaneous mutations that confer resistance. Chemists retaliate by modifying existing drugs or developing new classes of antibiotics, and the battles rage back and forth. In recent years, outbreaks of superbugs (in Chicago, Los Angeles, and other locations around the world) that are resistant to even the most powerful antibiotics and the decline in new antibiotics coming to market give evidence that the bacteria are winning.

Amoxicillin and other β -lactam antibiotics, as noted in Figure 13.18, are suicide inhibitors that inhibit by binding covalently and irreversibly to the bacterial enzymes involved in essential peptidoglycan-synthesizing enzymes. Bacteria respond to antibiotic challenge with β -lactamases that hydrolyze and inactivate the drug. For this reason, clavulanic acid, an irreversible inhibitor of β -lactamases, is often administered along with amoxicillin, to increase its effectiveness.

The designation as a superbug includes the bacteria that have developed resistance even to the carbapenems, a relatively new and particularly powerful class of antibiotics. These carbapenem-resistant Gram-negative pathogens (CRGNPs), including the Enterobacteriaceae, were involved in the outbreaks cited earlier. Carbapenem resistance in these organisms is ascribed to NDM-1, a metallo- β -lactamase (which depends on a catalytic Zn^{2+} in the active site). It is particularly concerning that the NDM-1 gene is

carried by a plasmid in many of the resistant strains that have been studied, allowing the gene to be transferred readily between different strains of bacteria, thus conferring antibiotic resistance to organisms that previously had none. Of even greater concern, no current drugs are effective against metallo- β -lactamases. However, Gerard Wright and colleagues have shown that aspergillomarasmine (AMA), a fungal metabolite, is a potent inhibitor of NDM-1, raising the intriguing possibility that AMA or a similar metallo- β -lactamase inhibitor may someday be used as a co-treatment with carbapenems as a useful therapy against superbugs.

potential energy barrier that separates reactant from product. Wave/particle duality in quantum theory implies that a wavelength λ can be calculated for a particle of mass m with a given kinetic energy E , according to the de Broglie equation:

$$\lambda = \frac{h}{\sqrt{2mE}} \quad (14.4)$$

where h is Planck's constant. Tunneling can only play a significant role in a reaction when the wavelength of the transferring particle is similar to the distance over which it is transferred. In such cases, the overlap of probability functions for the particle in the reactant and product states is sufficient to permit effective tunneling (Figure 14.13d).

In enzyme reactions, only electrons and hydrogen (H^+ , H^- , or $H\cdot$) satisfy this condition. Consider the low likelihood of tunneling for atoms larger than hydrogen. For example, the de Broglie wavelength of a carbon atom, with a mass of 12 Da, is approximately 0.25 Å, a distance too short for tunneling in any reaction involving carbon transfer. Note also that tunneling permits the transfer of electrons over substantial molecular distances. Assuming a kinetic energy of 10 kJ/mole, Equation 14.4 yields de Broglie wavelengths for the electron and hydrogen of 38 Å and 0.9 Å, respectively. The latter wavelength is on the order of distances involved in proton, hydrogen, and hydride transfers in enzyme reactions, and it's likely that tunneling is a contributing factor in most, if not all, hydrogen transfer reactions.

14.5g Metal Ion Catalysis

Many enzymes require metal ions for maximal activity. If the enzyme binds the metal very tightly or requires the metal ion to maintain its stable, native state, it is referred to as a **metalloenzyme**. Enzymes that bind metal ions more weakly, perhaps only during the catalytic cycle, are referred to as **metal activated**. One role for metals in metal-activated enzymes and metalloenzymes is to act as electrophilic catalysts, stabilizing the increased electron density or negative charge that can develop during reactions. Thermolysin is one of the enzymes that function in this manner (Figure 14.14). Another potential function of metal ions is to provide a powerful nucleophile at neutral pH. Coordination to a metal ion can increase the acidity of a nucleophile with an ionizable proton:

The reactivity of the coordinated, deprotonated nucleophile is typically intermediate between that of the un-ionized and ionized forms of free nucleophile. Carboxypeptidase, a protease that cleaves residues from the C-terminus of many proteins, contains an active site Zn^{2+} , which facilitates deprotonation of a water molecule in this manner.

14.5h Noncatalytic Residues May Still Play a Role in Catalysis in Enzyme Active Sites

Only about half of the common amino acid residues (the polar residues, especially those with dissociable protons—His, Cys, Asp, Glu, Arg, Lys, Tyr, Ser, Thr, Asn, and Gln) engage directly in catalytic effects in enzyme active sites. However, the catalytic actions of these residues can be influenced by other polar and charged residues at the active site

Figure 14.14 Thermolysin is an endoprotease (it cleaves polypeptides in the middle of the chain) with a catalytic Zn^{2+} ion in the active site. The Zn^{2+} ion stabilizes the buildup of negative charge on the peptide carbonyl oxygen, as a glutamate residue deprotonates water, promoting hydroxide attack on the carbonyl carbon. Thermolysin is found in certain laundry detergents, where it is used to remove protein stains from fabrics.

and even by hydrophobic residues. The so-called secondary, or noncatalytic, residues at enzyme active sites play a variety of roles:

- Raising or lowering catalytic residue pK_a values through electrostatic or hydrophobic interactions.
- Orientation of catalytic residues, as will be seen in the serine proteases, where Asp¹⁰² orients His⁵⁷ (see Figure 14.21).
- Charge stabilization, as will be seen in chorismate mutase, where active-site arginines stabilize negatively charged carboxyl groups on the substrate (see Figures 14.31 and 14.33).
- Proton transfers via hydrogen tunneling. In such quantum mechanical tunneling, the proton transfer is accomplished by molecular motions that lead to degeneracy of a pair of localized proton vibrational states (Figure 14.13). Proton tunneling can be facilitated by nearby molecular motions of secondary residues coupled to the motion and vibration of the bonds in question.

14.6 | What Can Be Learned from the Mechanisms of Some Typical Enzymes?

The rest of this chapter will be devoted to several classic and representative enzyme mechanisms, including those of the serine proteases, the aspartic proteases, and chorismate mutase. Both the serine proteases and the aspartic proteases use general acid-base catalysis chemistry; the serine proteases also employ a covalent catalysis strategy. Chorismate mutase, on the other hand, uses neither of these and depends instead on the formation of a NAC to carry out its reaction. These particular cases are well understood, because the three-dimensional structures of the enzymes and the bound substrates are known at atomic resolution and because great efforts have been devoted to kinetic and mechanistic studies. They are important because they represent reaction types that appear again and again in living systems and because they demonstrate many of the catalytic principles cited previously. Enzymes are the catalytic machines that sustain life, and what follows is an intimate look at the inner workings of the machinery.

14.6a Serine Proteases

Serine proteases are a class of proteolytic enzymes whose catalytic mechanism is based on an active-site serine residue. Serine proteases are one of the best-characterized families of enzymes. This family includes *trypsin*, *chymotrypsin*, *elastase*, *thrombin*, *subtilisin*, *plasmin*, *tissue plasminogen activator*, and other related enzymes. The first three of these are digestive enzymes and are synthesized in the pancreas and secreted into the digestive tract as inactive **proenzymes**, or **zymogens**. Within the digestive tract, the zymogen is converted into the active enzyme form by cleaving off a portion of the peptide chain. Thrombin is a crucial enzyme in the blood-clotting cascade, subtilisin is a bacterial protease, and plasmin breaks down the fibrin polymers of blood clots. Tissue plasminogen activator (TPA) specifically cleaves the proenzyme *plasminogen*, yielding plasmin. Due to its ability to stimulate breakdown of blood clots, TPA can minimize the harmful consequences of a heart attack if administered to a patient within 30 minutes of onset. Finally, although not itself a protease, *acetylcholinesterase* is a *serine esterase* and is related mechanistically to the serine proteases. It degrades the neurotransmitter acetylcholine in the synaptic cleft between neurons.

14.6b The Digestive Serine Proteases

Trypsin, chymotrypsin, and elastase all carry out the same reaction—the cleavage of a peptide chain—and although their structures and mechanisms are quite similar, they display very different specificities. Trypsin cleaves peptides on the carbonyl side of the basic amino acids, arginine or lysine. Chymotrypsin prefers to cleave on the carbonyl side of aromatic residues, such as phenylalanine and tyrosine. Elastase is not as specific as the other two; it mainly cleaves peptides on the carbonyl side of small,

Figure 14.15 Comparison of the amino acid sequences of chymotrypsinogen, trypsinogen, and elastase. Each circle represents one amino acid. Numbering is based on the sequence of chymotrypsinogen. *Filled circles* indicate residues that are identical in all three proteins. Disulfide bonds are indicated in *orange*. The positions of the three catalytically important active-site residues (His⁵⁷, Asp¹⁰², and Ser¹⁹⁵) are indicated. Scissors indicate positions of proteolytic cleavage that activates these enzymes.

neutral residues. These three enzymes all possess molecular weights in the range of 25,000, and all have similar sequences (Figure 14.15) and three-dimensional structures. The structure of chymotrypsin is typical of the three enzymes (Figure 14.16). The molecule is ellipsoidal in shape and contains an α -helix at the C-terminal end (residues 230 to 245) and several β -sheet domains. Most of the aromatic and hydrophobic residues are buried in the interior of the protein, and most of the charged or hydrophilic residues are on the surface. Three polar residues—His⁵⁷, Asp¹⁰², and Ser¹⁹⁵—form what is known as a **catalytic triad** at the active site (Figures 14.15, 14.16, and 14.17). These three residues are conserved in trypsin and elastase as well.

Figure 14.16 Structure of chymotrypsin (*white*) in a complex with eglin C (*blue ribbon*), a target protein. The residues of the catalytic triad (His⁵⁷, Asp¹⁰², and Ser¹⁹⁵) are highlighted. His⁵⁷ (*red*) is flanked by Asp¹⁰² (*gold*) and by Ser¹⁹⁵ (*green*). The catalytic site is filled by a peptide segment of eglin. Note how close Ser¹⁹⁵ is to the peptide that would be cleaved in the chymotrypsin reaction (PDB id = 1ACB).

Figure 14.17 The catalytic triad of chymotrypsin.

Figure 14.18 The substrate-binding pockets of trypsin (PDB id = 2CMY), chymotrypsin (PDB id = 1ACB), and elastase (PDB id = 3EST). Asp¹⁸⁹ (*aqua*) coordinates Arg and Lys residues of peptide substrates in the trypsin binding pocket. Val²¹⁶ (*purple*) and Thr²²⁶ (*green*) make the elastase binding pocket shallow and able to accommodate only small, nonbulky residues.

The active site is actually a depression on the surface of the enzyme, with a pocket that the enzyme uses to identify the residue for which it is specific (Figure 14.18). Chymotrypsin, for example, has a pocket surrounded by hydrophobic residues and large enough to accommodate an aromatic side chain. The pocket in trypsin has a negative charge (Asp¹⁸⁹) at its bottom, facilitating the binding of positively charged arginine and lysine residues. Elastase, on the other hand, has a shallow pocket with bulky threonine and valine residues at the opening. Only small, nonbulky residues can be accommodated in its pocket. In the active sites of all these enzymes, the backbone of the peptide substrate is hydrogen bonded in antiparallel fashion to residues 215 to 219 and bent so that the peptide bond to be cleaved is bound close to His⁵⁷ and Ser¹⁹⁵.

14.6c The Chymotrypsin Mechanism in Detail: Kinetics

Much of what is known about the chymotrypsin mechanism is based on studies of the hydrolysis of artificial substrates—simple organic esters, such as *p*-nitrophenylacetate (Figure 14.19). *p*-Nitrophenylacetate is an especially useful model substrate, because the nitrophenolate product is easily observed, due to its strong absorbance at 400 nm. When large amounts of chymotrypsin are used in kinetic studies with this substrate, a **rapid initial burst** of *p*-nitrophenolate is observed (in an amount approximately equal to the enzyme concentration), followed by a much slower, linear rate of nitrophenolate release (Figure 14.20a). Observation of a burst, followed by slower, steady-state product release, is strong evidence for a multistep mechanism, with a fast first step and a slower second step.

In the chymotrypsin mechanism, the nitrophenylacetate combines with the enzyme to form an ES complex. This is followed by a rapid step in which an **acyl-enzyme intermediate** is formed, with the acetyl group covalently bound to the very reactive Ser¹⁹⁵. The nitrophenyl moiety is released as nitrophenolate (Figure 14.20b, fast step), accounting for the burst of nitrophenolate product. Attack of a water molecule on the acyl-enzyme intermediate yields acetate as the second product in a subsequent, slower step. The enzyme is now free to bind another molecule of *p*-nitrophenylacetate, and the *p*-nitrophenolate product produced at this point corresponds to the slower, steady-state formation of product (Figure 14.20a). In this mechanism, the release of acetate is the **rate-limiting step** and accounts for the observation of **burst kinetics**.

14.6d The Serine Protease Mechanism in Detail: Events at the Active Site

A likely mechanism for peptide hydrolysis by chymotrypsin is shown in Figure 14.21. As the backbone of the substrate peptide binds adjacent to the catalytic triad, the specific side chain fits into its pocket (step 1). Asp¹⁰² of the catalytic triad positions

p-Nitrophenylacetate

Figure 14.19 Chymotrypsin cleaves simple esters, in addition to peptide bonds. *p*-Nitrophenylacetate has been used in studies of the chymotrypsin mechanism. The cleavage site is indicated with the pink scissors.

Figure 14.20 Burst kinetics observed in the chymotrypsin reaction with *para*-nitrophenylacetate. **(a)** A burst of nitrophenolate is followed by a slower, steady-state release. After an initial lag period, acetate release is observed. This kinetic pattern is consistent with the scheme in **(b)**: rapid formation of an acyl-enzyme intermediate (and the burst of nitrophenolate). The slower, steady-state release of products corresponds to rate-limiting breakdown of the acyl-enzyme intermediate.

His⁵⁷ and immobilizes it through a hydrogen bond as shown. In step 2, His⁵⁷ acts as a general base to withdraw a proton from Ser¹⁹⁵, facilitating nucleophilic attack by Ser¹⁹⁵ on the carbonyl carbon of the peptide bond to be cleaved. This is probably a *concerted step*, because proton transfer prior to Ser¹⁹⁵ attack on the acyl carbon would leave a relatively unstable negative charge on the serine oxygen. In step 3, donation of a proton from His⁵⁷ to the peptide's amide nitrogen creates a protonated amine on the covalent, tetrahedral intermediate, facilitating the subsequent bond breaking (step 4) and dissociation of the amine product (step 5). The negative charge on the peptide oxygen is unstable; the tetrahedral intermediate is short lived and rapidly breaks down to expel the amine product. The acyl-enzyme intermediate that results is reasonably stable; it can even be isolated using substrate analogs for which further reaction cannot occur. With normal peptide substrates, however, subsequent nucleophilic attack at the carbonyl carbon by water (step 6) generates another transient tetrahedral intermediate (Figure 14.21g). His⁵⁷ acts as a general base in this step, accepting a proton from the attacking water molecule. The subsequent collapse of the tetrahedral intermediate (step 7) is assisted by proton donation from His⁵⁷ to the serine oxygen in a concerted manner. Deprotonation of the carboxyl group and its departure from the active site (step 8) complete the reaction as shown.

Asp¹⁰² does not appear to interact directly with the substrate. The catalytic role of Asp¹⁰² in trypsin and the other serine proteases had been surmised on the basis of its proximity to His⁵⁷ in structures obtained from X-ray diffraction studies, but it had never been demonstrated with certainty in physical or chemical studies. As can be seen in Figure 14.16, Asp¹⁰² is buried at the active site; it is normally inaccessible to chemical modifying reagents. In 1987, Charles Craik, William Rutter, and their colleagues used site-directed mutagenesis to prepare a mutant trypsin with an asparagine in place of Asp¹⁰². This mutant trypsin possessed a hydrolytic activity with ester substrates only 1/10,000 that of native trypsin, demonstrating that Asp¹⁰² is indeed essential for catalysis and that its ability to immobilize and orient His⁵⁷ by formation of a hydrogen bond is crucial to the function of the catalytic triad.

Figure 14.21 A detailed mechanism for the chymotrypsin reaction. Note the low-barrier hydrogen bond (LBHB) in (c) and (g).

The serine protease mechanism relies in part on a low-barrier hydrogen bond between Asp¹⁰² and His⁵⁷. In the free enzyme, the p*K*_a values of Asp¹⁰² and His⁵⁷ are very different, and the H bond between them is a weak one. However, donation of the proton of Ser¹⁹⁵ to His⁵⁷ lowers the p*K*_a of the protonated imidazole ring so it becomes a close match to that of Asp¹⁰², and the H bond between them becomes an LBHB. The energy released in the formation of this LBHB is used to facilitate the formation of the subsequent tetrahedral intermediate (Figure 14.21c, g).

14.6e The Aspartic Proteases

Mammals, fungi, and higher plants produce a family of proteolytic enzymes known as **aspartic proteases**. These enzymes are active at acidic (or sometimes neutral) pH, and each possesses two aspartic acid residues at the active site. Aspartic proteases carry out a variety of functions (Table 14.3), including digestion (*pepsin* and *chymosin*), lysosomal protein degradation (*cathepsin D* and *E*), and regulation of blood pressure (*renin* is an aspartic protease involved in the production of *angiotensin*, a hormone that stimulates smooth muscle contraction and reduces excretion of salts and fluid). The aspartic proteases display a variety of substrate specificities, but normally they are most active in the cleavage of peptide bonds between two hydrophobic amino acid residues. The preferred substrates of pepsin, for example, contain aromatic residues on both sides of the peptide bond to be cleaved.

Most aspartic proteases are composed of 323 to 340 amino acid residues, with molecular weights near 35,000 Da. Aspartic protease polypeptides consist of two homologous domains that fold to produce a tertiary structure composed of two similar lobes, with approximate twofold symmetry (Figure 14.22). Each of these lobes or domains consists of two β -sheets and two short α -helices. The two domains are bridged and connected by a six-stranded, antiparallel β -sheet. The active site is a deep and extended cleft, formed by the two juxtaposed domains and large enough to accommodate about seven amino acid residues. The two catalytic aspartate residues, residues 32 and 215 in porcine pepsin, for example, are located deep in the center of the active site cleft. The N-terminal domain forms a flap that extends over the active site, which may help to immobilize the substrate in the active site.

On the basis, in part, of comparisons with chymotrypsin, trypsin, and the other serine proteases, it was at first hypothesized that aspartic proteases might function by formation of covalent enzyme–substrate intermediates involving the active-site aspartate residues. However, all attempts to trap or isolate a covalent intermediate failed, and a mechanism (see following section) favoring noncovalent enzyme–substrate intermediates and general acid–general base catalysis is now favored for aspartic proteases.

Figure 14.22 Symmetry and pseudosymmetry in the aspartic proteases. Structures of (a) HIV-1 protease, a dimer (PDB id = 7HVP), and (b) pepsin, a monomer. Pepsin’s N-terminal half is shown in red; C-terminal half is shown in blue (PDB id = 5PEP).

Table 14.3 Some Representative Aspartic Proteases		
Name	Source	Function
Pepsin*	Stomach	Digestion of dietary protein
Chymosin†	Stomach	Digestion of dietary protein
Cathepsin D	Spleen, liver, and many other animal tissues	Lysosomal digestion of proteins
Renin‡	Kidney	Conversion of angiotensinogen to angiotensin I; regulation of blood pressure
HIV-protease§	AIDS virus	Processing of AIDS virus proteins

*The second enzyme to be crystallized (by John Northrop in 1930). Even more than urease before it, pepsin study by Northrop established that enzyme activity comes from proteins.
 †Also known as rennin, it is the major pepsinlike enzyme in gastric juice of fetal and newborn animals. It has been used for thousands of years, in a gastric extract called rennet, in the making of cheese.
 ‡A drop in blood pressure causes release of renin from the kidneys, which converts more angiotensinogen to angiotensin.
 §A dimer of identical monomers, homologous to pepsin

14.6f The Mechanism of Action of Aspartic Proteases

A crucial piece of evidence supporting the general acid-base model is the pH dependence of protease activity (Figure 14.23). For many years, enzymologists hypothesized that the aspartate carboxyl groups functioned alternately as general acid and general base. This model requires that one of the aspartate carboxyls be protonated and one be deprotonated when substrate binds. (This made sense because X-ray diffraction data on aspartic proteases had shown that the active-site structure in the vicinity of the two aspartates is highly symmetric.) However, Stefano Piana and Paolo Carloni reported in 2000 that molecular dynamics simulations of aspartic proteases were consistent with a low-barrier hydrogen bond involving the two active-site aspartates. This led to a new mechanism for the aspartic proteases (Figure 14.24) that begins with Piana and Carloni's model of the LBHB structure of the free enzyme (state E). In this model, the LBHB holds the twin aspartate carboxyls in a coplanar conformation, with the catalytic water molecule on the opposite side of a ten-atom cyclic structure.

Following substrate binding, a counterclockwise flow of electrons moves two protons clockwise and creates a tetrahedral intermediate bound to a diprotonated enzyme form (FT). Then a clockwise movement of electrons moves two protons counterclockwise and generates the zwitterion intermediate bound to a monoprotonated enzyme form (ET'). Collapse of the zwitterion cleaves the C—N bond of the substrate. Dissociation of one product leaves the enzyme in the diprotonated FQ form. Finally, deprotonation and rehydration lead to regeneration of the ten-atom cyclic structure, E.

What is the purpose of the low-barrier hydrogen bond in the aspartic protease mechanism? It may be to disperse electron density in the ten-atom cyclic structure, accomplishing rate acceleration by means of hydrogen tunneling (Figure 14.25). The barrier between the ES and ET' states of Figure 14.24 is imagined to be large, and the state FT may not exist as a discrete intermediate but rather may exist transiently to facilitate conversion of ES and ET'.

14.6g The HIV-1 Protease Is an Aspartic Protease

Recent research on acquired immunodeficiency syndrome (AIDS) and its causative viral agent, the human immunodeficiency virus (HIV-1), has brought a new aspartic protease to light. **HIV-1 protease** cleaves the polyprotein products of the HIV-1 genome, producing several proteins necessary for viral growth and cellular infection (Figure 14.26). HIV-1 protease cleaves several different peptide linkages. For example, the protease cleaves between the Tyr and Pro residues of the sequence Ser-Gln-Asn-Tyr-Pro-Ile-Val, which joins the p17 and p24 HIV-1 proteins.

Figure 14.23 pH-rate profiles for (a) pepsin and (b) HIV protease. (Adapted from Denburg, J., et al., 1968. The effect of pH on the rates of hydrolysis of three acylated dipeptides by pepsin. *Journal of the American Chemical Society* **90**:479–486; and Hyland, J., et al., 1991. Human immunodeficiency virus-1 protease 2. Use of pH rate studies and solvent kinetic isotope effects to elucidate details of chemical mechanism. *Biochemistry* **30**:8454–8463.)

Figure 14.24 Mechanism for the aspartic proteases. The letter titles describe the states as follows: E represents the enzyme form with a low-barrier hydrogen bond between the catalytic aspartates, F represents the enzyme form with both aspartates protonated and joined by a conventional hydrogen bond, S represents bound substrate, T represents a tetrahedral amide hydrate intermediate, P represents bound carboxyl product, and Q represents bound amine product. This mechanism is based on a mechanism proposed by Dexter Northrop, a distant relative of John Northrop, who had first crystallized pepsin in 1930 and the data of Thomas Meek. (Northrop, D. B., 2001. Follow the protons: a low-barrier hydrogen bond unifies the mechanisms of the aspartic proteases. *Accounts of Chemical Research* **34**:790–797. Meek, T. D., Catalytic mechanisms of the aspartic proteinases. In Sinnott, M., ed, *Comprehensive Biological Catalysis: A Mechanistic Reference*, San Diego: Academic Press, 1998.)

Figure 14.25 Energy level diagram for the aspartic protease reaction, showing ground-state hydrogen tunneling (arrow), with consequent rate acceleration.

Figure 14.26 HIV mRNA provides the genetic information for synthesis of a polyprotein. Proteolytic cleavage of this polyprotein by HIV protease produces the individual proteins required for viral growth and cellular infection.

The HIV-1 protease is a remarkable viral imitation of mammalian aspartic proteases: It is a **dimer of identical subunits** that mimics the two-lobed monomeric structure of pepsin and other aspartic proteases. The HIV-1 protease subunits are 99-residue polypeptides that are homologous with the individual domains of the monomeric proteases. Structures determined by X-ray diffraction studies reveal

Critical Developments in Biochemistry

Frances Arnold and Directed Evolution of Enzymes

Enzymes have been evolving naturally since the emergence of life on Earth, changing slowly to improve the fitness of organisms. The methods of **directed evolution** were developed in laboratories in the 1990s to speed the evolutionary process, producing enzymes that catalyze useful and novel reactions. The methodology developed by Frances Arnold at Caltech is based on several steps: 1) selection of a suitable starting enzyme with properties similar to the desired one; 2) use of an error-prone (low fidelity) DNA polymerase to construct a DNA library of mutated versions of the gene for the starting enzyme; 3) insertion of these mutant genes into bacteria, each expressing a slightly different version of the starting enzyme; and screening to test the activity of each of the resulting modified enzymes. The genes for enzymes with even slightly improved activity are subjected to additional rounds of random mutation, expression, and testing. Arnold showed that successive generations of this process could lead to dramatic increases in the catalytic prowess of these evolved enzymes.

For an enzyme of a few hundred residues, allowing just one or two mutations per variant would require testing of a few thousand

new enzyme candidates. At the same time, Arnold found that useful traits could emerge after as few as five to ten iterations of mutagenesis and selection, and her protocol was adopted rapidly and modified in laboratories around the world. Directed evolution has produced enzymes that synthesize fuels, pharmaceuticals, and industrial and agricultural chemicals. Other applications have developed therapeutic and diagnostic enzymes and gene editing tools. In recognition of her pioneering accomplishments, Frances Arnold shared in the Nobel Prize in Chemistry in 2018. She noted at the time, “I wanted to rewrite the code of life, to make new molecular machines that would solve human problems.”

that the active site of HIV-1 protease is formed at the interface of the homodimer and consists of two aspartate residues, designated Asp²⁵ and Asp^{25'}, one contributed by each subunit (Figure 14.27). In the homodimer, the active site is covered by two identical flaps, one from each subunit, in contrast to the monomeric aspartic proteases, which possess only a single active-site flap. Enzyme kinetic measurements by Thomas Meek and his collaborators at SmithKline Beecham Pharmaceuticals have shown that the mechanism of HIV-1 protease is very similar to those of other aspartic proteases.

14.6h Chorismate Mutase: A Model for Understanding Catalytic Power and Efficiency

Direct comparison of an enzyme reaction with the analogous uncatalyzed reaction is usually difficult, if not impossible. There are several problems: First, many enzyme-catalyzed reactions do not proceed at measurable rates in the absence of the enzyme. Second, many enzyme-catalyzed reactions involve formation of a covalent intermediate between the enzyme and the substrate. Third, a reaction occurring in an enzyme active site might proceed through a different transition state than the corresponding solution reaction. **Chorismate mutase**, which catalyzes a concerted intramolecular rearrangement of chorismate to prephenate in the biosynthesis of phenylalanine in microorganisms and plants, is

Figure 14.27 HIV-1 protease complexed with the inhibitor Crixivan (red) made by Merck. (Left) The flaps (residues 46–55 from each subunit) covering the active site are shown in green, and the active-site aspartate residues involved in catalysis are shown in light purple. (Right) The close-up of the active site shows the interaction of Crixivan with the carboxyl groups (yellow) of the essential aspartate residues (PDB id = 1HSG).

an exception to all these potential problems. First, although the rate of the enzyme-catalyzed reaction is more than a million times faster, the uncatalyzed solution reaction still proceeds at reasonable and measurable rates. Second, the enzyme reaction does not employ a covalent intermediate. In this simple reaction, one carbon–oxygen bond is broken, and one carbon–carbon bond is formed. It is an example of a Claisen rearrangement, familiar to any student of organic chemistry (Figure 14.28).

What about the transition states for the catalyzed and uncatalyzed reactions? There are two possible transition states, one involving a chair conformation and the other a boat (Figure 14.29). Jeremy Knowles and his co-workers have shown that both the enzymatic and the solution reactions take place via a chair transition state, and a transition-state analog of this state has been characterized (Figure 14.29).

The Chorismate Mutase Active Site Lies at the Interface of Two Subunits The chorismate mutase from *Escherichia coli* is the N-terminal portion (109 residues) of a bifunctional enzyme, termed the **P protein**, which also has a C-terminal prephenate dehydrogenase activity. The N-terminal portion of the P protein has been prepared as a separate protein

(a) Chorismate mutase reaction

(b) Classic Claisen rearrangement

Figure 14.28 The chorismate mutase reaction is a Claisen rearrangement. **(a)** The chorismate mutase reaction converts chorismate to prephenate. **(b)** A classic Claisen rearrangement. Conversion of allyl phenyl ether to 2-allyl alcohol proceeds through a cyclohexadienone intermediate, which then undergoes a keto-enol tautomerization.

Figure 14.29 The conversion of chorismate to prephenate could occur (in principle) through a boat transition state or a chair transition state. The difference can be understood by imagining two different isotopes of hydrogen (*blue* and *green*) at carbon 9 of chorismate and the products that would result in each case. Knowles and co-workers have shown that both the uncatalyzed reaction and the reaction on chorismate mutase occur through a chair transition state. The molecule shown at right is a transition state analog for the chorismate mutase reaction.

by recombinant DNA techniques, and this engineered protein is a fully functional chorismate mutase. The structure shown in Figure 14.30 is a homodimer, each monomer consisting of three α -helices (denoted H1, H2, and H3) connected by short loops. The two monomers are dovetailed in the dimer structure, with the H1 helices paired and the H3 helices overlapping significantly. The long, 10-turn H1 helices form an antiparallel coiled coil, with leucines at positions 10, 17, 24, and 31 in a classic 7-residue repeat pattern.

The chorismate mutase dimer contains two equivalent active sites, each formed from portions of both monomers. The structure shown in Figure 14.30 contains a bound transition-state analog (Figure 14.29) stabilized by 12 electrostatic and hydrogen-bonding interactions (Figure 14.31). Arg²⁸ from one subunit and Arg^{11*} from the other coordinate the carboxyl groups of the analog, and a third arginine (Arg⁵¹) coordinates a water molecule, which in turn coordinates both carboxyls of the analog. Each oxygen of the analog is coordinated by two groups from the active site. In addition, there are hydrophobic residues surrounding the analog, especially Val³⁵ on one side and Ile⁸¹ and Val⁸⁵ on the other.

The Chorismate Mutase Active Site Favors a Near-Attack Conformation The chorismate mutase reaction mechanism requires that the carboxyvinyl group fold over the

Figure 14.30 Chorismate mutase is a symmetric homodimer, each monomer consisting of three α -helices connected by short loops. **(a)** The dimer contains two equivalent active sites, each formed from portions of both monomers (PDB id = 4CSM). **(b)** A close-up of the active site, showing the bound transition-state analog (pink, see Figure 14.29).

Atomic structure of the buried catalytic pocket of *Escherichia coli* chorismate mutase. *Journal of the American Chemical Society* 117:3627–3628.)

Human Biochemistry

Protease Inhibitors-Game Changers for AIDS Patients

Infection with HIV was once considered a death sentence, but the emergence of a new family of drugs called protease inhibitors has made it possible for some AIDS patients to improve their overall health and extend their lives. These drugs are all specific inhibitors of the HIV-1 protease. By inhibiting the protease, they prevent the development of new virus particles in the cells of infected patients. A combination of drugs—including a protease inhibitor together with a reverse transcriptase inhibitor like AZT—can reduce the human immunodeficiency virus (HIV) to undetectable levels in about 40% to 50% of infected individuals. Patients who respond successfully to this combination therapy have experienced dramatic improvement in their overall health and a substantially lengthened life span.

Four of the protease inhibitors approved for use in humans by the U.S. Food and Drug Administration are shown in the figures: Crixivan by Merck, Invirase by Hoffman-LaRoche, Norvir by Abbott, and Viracept by Agouron. These drugs were all developed from a structure-based design strategy; that is, the drug molecules were designed to bind tightly to the active site of the HIV-1 protease. The backbone OH-group in all these substances inserts between the two active-site carboxyl groups of the protease.

In the development of an effective drug, it is not sufficient merely to show that a candidate compound can cause the desired

biochemical effect. It must also be demonstrated that the drug can be effectively delivered in sufficient quantities to the desired site(s) of action in the organism and that the drug does not cause undesirable side effects. The HIV-1 protease inhibitors shown here fulfill all of these criteria. Other drug candidates have been found that are even better inhibitors of HIV-1 protease in cell cultures, but many of these fail the test of bioavailability—the ability of a drug to be delivered to the desired site(s) of action in the organism.

Candidate protease inhibitor drugs must be relatively specific for the HIV-1 protease. Many other aspartic proteases exist in the human body and are essential to a variety of body functions, including digestion of food and processing of hormones. An ideal drug thus must strongly inhibit the HIV-1 protease, must be delivered effectively to the lymphocytes where the protease must be blocked, and should not adversely affect the activities of the essential human aspartic proteases.

A final but important consideration is viral mutation. Certain mutant HIV strains are resistant to one or more of the protease inhibitors, and even for patients who respond initially to protease inhibitors, it is possible that mutant viral forms may eventually arise and thrive in infected individuals. The search for new and more effective protease inhibitors is ongoing.

Invirase (saquinavir)

Crixivan (indinavir)

Viracept (nelfinavir mesylate)

Norvir (ritonavir)

chorismate ring to facilitate the Claisen rearrangement (Figure 14.32). This implies the formation of a NAC on the way to the transition state. Bruice and his co-workers have carried out extensive molecular dynamics simulations of the chorismate mutase reaction. Their calculations show that in the nonenzymatic reaction, only 0.0001% of chorismate in solution exists in the NAC required for reaction. Similar calculations show that in the enzyme active site, chorismate adopts a NAC 30% of the time. The computer-simulated NAC in the chorismate mutase active site (Figure 14.33) is similar in many ways to the chorismate mutase-TSA complex, with Arg²⁸ and Arg¹¹ coordinating the two carboxylate groups of chorismate so as to position the carboxyvinyl group in the conformation required for transition-state formation. This conformation is also stabilized by Val³⁵ and Ile⁸⁵, which are in van der Waals contact with the vinyl group and the chorismate ring, respectively. Thus, the NAC of chorismate is promoted by electrostatic and hydrophobic interactions with active-site residues.

Figure 14.32 The mechanism of the chorismate mutase reaction. The carboxyvinyl group folds up and over the chorismate ring, and the reaction proceeds via an internal rearrangement.

Figure 14.33 Chorismate bound to the active site of chorismate mutase in a structure that resembles a NAC. Arrows indicate hydrophobic interactions, and red dotted lines indicate electrostatic interactions. (Adapted from Hur, S., and Bruice, T., 2003. The near attack conformation approach to the study of the chorismate to prephenate reaction. *Proceedings of the National Academy of Sciences USA* **100**:12015–12020.)

Figure 14.34 The energetic profile of the chorismate mutase reaction. Computer simulations by Bruice and his co-workers show that the NAC and the E-S complex are separated by only 0.42 kJ/mol, meaning that the NAC forms much more readily in the enzyme active site than it does in the absence of enzyme. The NAC and the reaction transition state are separated by similar energy barriers in either the presence or the absence of the enzyme. Thus, the catalytic prowess of the enzyme lies in its ability to form the NAC at a very small energetic cost. (Adapted from Bruice, T., 2002. A view at the millennium: the efficiency of enzymatic catalysis. *Accounts of Chemical Reactions* 35:139–148.)

The energetics of the chorismate mutase reaction are revealing (Figure 14.34). Computer simulations by Bruice and his co-workers show that formation of a NAC in the absence of the enzyme is energetically costly, whereas formation of the NAC in the enzyme active site is facile, with only a modest energy cost. On the other hand, the energy required to move from the NAC to the transition state is about the same for the solution and the enzyme reactions. Clearly, the catalytic advantage of chorismate mutase is the ease of formation of a NAC in the active site.

Foundational Biochemistry Things You Should Know after Reading Chapter 14.

- Enzyme-catalyzed reactions are typically 10^7 to 10^{15} times faster than their uncatalyzed counterparts; the alkylsulfatase from *Corynebacterium Bla* exhibits a rate acceleration of 2×10^{26} .
- Linus Pauling was the first to postulate that the active sites of enzymes bind the transition state more tightly than the substrate or product.
- The catalytic role of enzymes is to reduce the energy barrier between substrate and transition state. In terms of free energies of activation, $\Delta G_e^\ddagger < \Delta G_u^\ddagger$.
- The intrinsic binding energy of the ES complex is typically compensated by loss of entropy due to binding of S to E, and destabilization of ES by strain, distortion, and de-solvation of the substrate.
- The dissociation constants for transition states from their enzymes are postulated to be in the range of 10^{-20} to 10^{-26} M.
- Transition state analogs are stable molecules that are chemically and structurally similar to the transition state and bind more strongly than substrates and competitive inhibitors.
- Enzymes facilitate formation of near-attack conformations (NACs), in which reacting atoms are in van der Waals contact and at an angle resembling the bond to be formed in the transition state.
- Protein motions are essential to enzyme catalysis. They assist substrate binding, bring catalytic groups into position around substrates, induce formation of NACs, assist in bond making and bond breaking, and facilitate conversion of substrate(s) to product(s).
- Some enzyme reactions derive much of their rate acceleration from the formation of covalent bonds between enzyme and substrate.
- General acid-base catalysis is catalysis in which a proton or OH^- is transferred in the transition state of a reaction.
- Stabilization energy released in the formation of low-barrier hydrogen bonds can lower the activation barrier for a reaction.
- Quantum mechanical tunneling is a contributing factor in most, if not all, hydrogen transfer reactions.
- Metal ions play a variety of catalytic roles in many enzymes.
- The serine proteases employ both covalent catalysis and general acid-base catalysis to catalyze peptide bond cleavage.
- Observation of burst kinetics is evidence for involvement of a covalent intermediate in an enzyme reaction.
- The serine protease mechanism involves two cycles of formation and collapse of tetrahedral intermediates.
- The mechanisms of aspartic proteases involve general acid-base catalysis and formation and breakdown of low-barrier hydrogen bonds, but not covalent catalysis.
- Human aspartic proteases are monomeric enzymes with pseudo-symmetric structures. The HIV-1 protease is a symmetric homodimer.
- Chorismate mutase is an enzyme that provides a direct comparison of enzyme-catalyzed and uncatalyzed reactions; rate acceleration by this enzyme appears to be due entirely to formation of a near-attack conformation in the enzyme active site.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. **Characterizing a Covalent Enzyme Inhibitor** Tosyl-L-phenylalanine chloromethyl ketone (TPCK) specifically inhibits chymotrypsin by covalently labeling His⁵⁷.

Tosyl-L-phenylalanine chloromethyl ketone (TPCK)

- Propose a mechanism for the inactivation reaction, indicating the structure of the product(s).
 - State why this inhibitor is specific for chymotrypsin.
 - Propose a reagent based on the structure of TPCK that might be an effective inhibitor of trypsin.
2. **Using Site-Directed Mutants to Understand an Enzyme Mechanism** In this chapter, the experiment in which Craik and Rutter replaced Asp¹⁰² with Asn in trypsin (reducing activity 10,000-fold) was discussed.
- On the basis of your knowledge of the catalytic triad structure in trypsin, suggest a structure for the uncatalytic triad of Asn-His-Ser in this mutant enzyme.
 - Explain why the structure you have proposed explains the reduced activity of the mutant trypsin.

- See the original journal articles (Sprang, et al., 1987. *Science* 237:905–909; and Craik, et al., 1987. *Science* 237:909–913) to see Craik and Rutter's answer to this question.
3. **Serine vs. Cysteine or Threonine** Give a possible explanation as to why serine is often a critically important residue in an enzyme's active site, but cysteine and structurally similar threonine are not.
4. **Assessing the Action of an Aspartic Protease Inhibitor** Pepstatin (see below) is an extremely potent inhibitor of the monomeric aspartic proteases, with K_i values of less than 1 nM.
- On the basis of the structure of pepstatin, suggest an explanation for the strongly inhibitory properties of this peptide.
 - Would pepstatin be expected to also inhibit the HIV-1 protease? Explain your answer.

5. **Aspartic Proteases** The structures of several ACE inhibitors are shown in the figure (also see A Deeper Look: Transition-State Analogs Make Our World Better and Section 14.6e). Find the common structural features for these compounds and explain why they are inhibitors of aspartic proteases.

6. **Deriving an Expression for Catalytic Power** Based on the following reaction scheme, derive an expression for k_c/k_u , the ratio of the rate constants for the catalyzed and uncatalyzed reactions, respectively, in terms of the free energies of activation for the catalyzed ($\Delta G_c^\ddagger$) and the uncatalyzed ($\Delta G_u^\ddagger$) reactions.

7. Comparison of Enzymatic and Nonenzymatic Rate Constants

The k_{cat} for alkaline phosphatase-catalyzed hydrolysis of methylphosphate is approximately 14/s at pH 8 and 25°C. The rate constant for the uncatalyzed hydrolysis of methylphosphate under the same conditions is approximately 10^{-15} /s. What is the difference in the free energies of activation of these two reactions?

- 8. Understanding the Actions of Proteolytic Enzymes** Active α -chymotrypsin is produced from chymotrypsinogen, an inactive precursor, as shown in the color figure. The first intermediate— π -chymotrypsin—displays chymotrypsin activity. Suggest proteolytic enzymes that might carry out these cleavage reactions effectively.

- 9. Understanding the Mechanism of Carboxypeptidase A** Consult the classic paper by William Lipscomb (1982, *Accounts of Chemical Research* 15:232–238), and on the basis of this article write a simple mechanism for the enzyme carboxypeptidase A.

10. Calculation of Rate Enhancement from Energies of Activation

The relationships between the free energy terms defined in the solution to Problem 4 earlier are shown in the following figure:

If the energy of the ES complex is 10 kJ/mol lower than the energy of E + S, the value of $\Delta G_c^\ddagger$ is 20 kJ/mol, and the value of $\Delta G_u^\ddagger$ is 90 kJ/mol, what is the rate enhancement achieved by an enzyme in this case?

11. Understanding the Implications of Transition State Stabilization

As noted in Section 14.4, a true transition state can bind to an enzyme active site with a K_T as low as 7×10^{-26} M. This is a remarkable number, with interesting consequences. Consider a hypothetical solution of an enzyme in equilibrium with a ligand that binds with a K_D of 10^{-27} M. If the concentration of free enzyme, [E], is equal to the concentration of the enzyme–ligand complex, [EL], what would [L], the concentration of free ligand, be? Calculate the volume of solution that would hold one molecule of free ligand at this concentration.

- 12. Substrate vs. Transition State** An enzyme is known to bind compounds A and B with K_S values of 0.15 mM and 0.01 mM, respectively. The mechanism of the enzymatic reaction for compound A is shown in the figure. Although difficult to determine, the K_T values for both compounds were estimated to be 5×10^{-24} M and 1×10^{-20} M, respectively.

- Explain the differences in K_T values between the two compounds?
- What would be the effect on the enzymatic activity if the enzyme was incubated with a mix of both compounds A and B?

- 13. Understanding the Very Tight Binding of Transition States** Another consequence of tight binding (problem 11) is the free energy change for the binding process. Calculate ΔG° for an equilibrium with a K_D of 10^{-27} M. Compare this value to the free energies of the noncovalent and covalent bonds with which you are familiar. What are the implications of this number, in terms of the binding of a transition state to an enzyme active site?

- 14. Meaning of Dissociation Constants** An enzyme E binds to a ligand L with a dissociation constant $K_D = \{[E][L]/[EL]\} = 10^{-21}$ M. It is tempting to assume that if the enzyme is fully saturated with L, then $[E] = [EL]$ and that the concentration of free ligand is $[L] = K_D = 10^{-21}$ M.

- What is wrong with this assumption?
- What is the correct relationship between these four parameters?
- What is the concentration of free ligand? What can be calculated from the information given?

(Hint: Revisit Section 13.3 for clues.)

- 15. Quantum Tunneling** In Section 14.5f, de Broglie wavelengths for an electron and a proton were calculated using Equation 14.4 and assuming a kinetic energy of 10 kJ/mole. Deuterium (D) is sometimes used to probe the mechanism of enzymatic catalysis. What is the de Broglie wavelength of D? The mass of D is 3.343584×10^{-27} kg, Planck's constant h is $6.6207004 \times 10^{-34}$ (m²kg)/s and $1 \text{ J} = 1 \text{ (m}^2\text{kg)}/\text{s}^2$.

- 16. Effect of Environment on Enzyme Activity** Apart from changes in pH, temperature, or salts, what other factor or factors could diminish the activity of an enzyme?

- 17. Assessing the Metabolic Consequences of Life without Enzymes** The incredible catalytic power of enzymes can perhaps best be appreciated by imagining how challenging life would be without just one of the thousands of enzymes in the human body. For example, consider life without fructose-1,6-bisphosphatase, an enzyme in the gluconeogenesis pathway in liver and kidneys (see Chapter 22), which helps produce new glucose from the food we eat:

The human brain requires glucose as its only energy source, and the typical brain consumes about 120 g (or 480 kilocalories) of glucose daily. Ordinarily, two pieces of sausage pizza could provide more than enough potential glucose to feed the brain for a day. According

to a national fast-food chain, two pieces of sausage pizza provide 1340 kilocalories, 48% of which is from fat. Fats cannot be converted to glucose in gluconeogenesis, so that leaves 697 kilocalories potentially available for glucose synthesis. The first-order rate constant for the hydrolysis of fructose-1,6-bisphosphate in the absence of enzyme is $2 \times 10^{-20}/\text{sec}$. Calculate how long it would take to provide enough glucose for one day of brain activity from two pieces of sausage pizza without the enzyme.

The following graphs show the temperature and pH dependencies of four enzymes, A, B, X, and Y. Problems 18 through 24 refer to these graphs.

18. Enzymes X and Y in the figure are both protein-digesting enzymes found in humans. Where would each enzyme most likely be at work, in the mouth, stomach, or the small intestine?
19. Which statement is true concerning enzymes X and Y?
 - a. They could not possibly be at work in the same part of the body at the same time.
 - b. They have different temperature ranges at which they work best.
 - c. At a pH of 4.5, enzyme X works slower than enzyme Y.
 - d. At their appropriate pH ranges, both enzymes work equally fast.
20. What conclusion may be drawn concerning enzymes A and B? Could one or both be human enzymes?
21. At which temperatures might enzymes A and B both work?
22. An enzyme–substrate complex can form when the substrate(s) bind(s) to the active site of the enzyme. Which environmental condition might alter the conformation of each enzyme (A, B, X, or Y) to the extent that its substrate is unable to bind?

23. At 35°C, the rate of the reaction catalyzed by enzyme A begins to level off. Which hypothesis best explains this observation?
 - a. The temperature is too far below optimum.
 - b. The enzyme has become saturated with substrate.
 - c. Both A and B.
 - d. Neither A nor B.
24. At what environmental conditions would digestive enzyme Y be unable to bring its substrate(s) to the transition state?
25. Review the mechanisms of the serine and aspartic proteases, and compare these two mechanisms carefully. Are there steps in the mechanisms that are similar? How are they similar? How are they different? Suggest experiments that could support or refute your hypotheses.
26. Consult the following reference (Samanta, U. and Bahnson, B. J., 2008. Crystal structure of human plasma platelet-activating factor acetylhydrolase. *Journal of Biological Chemistry* **283**:31617–31624), consider the active-site structure of this enzyme in the light of material in this chapter, and write a detailed mechanism for the PAF acetylhydrolase.
27. Superbug infections are becoming more common around the world. Many of these infections arise from the action of β -lactamases, of which there are several types with different mechanisms of action. Consult the end-of-chapter reference by von Nussbaum and Schiffer and write detailed mechanisms for the serine β -lactamases and metallo- β -lactamases.
28. A kinase reaction—the transfer of a phosphoryl group from ATP to a substrate—would take thousands of years to complete under normal conditions without an enzyme, but enzymes carry out phosphoryl transfers in milliseconds! Understanding how such rate enhancements might occur is one of the ultimate goals of biochemical science. Dorothee Kern and her colleagues have provided intriguing new insights about enzyme catalysis by studying the microscopic steps in the catalytic cycle of adenylate kinase, which catalyzes the reaction: $\text{ATP} + \text{AMP} \rightleftharpoons 2\text{ADP}$. Consult the following reference (Kerns, S. J., et al., 2015. The energy landscape of adenylate kinase during catalysis. *Nature Structural and Molecular Biology* **22**:124–131.) and describe the experimental methods used and the conclusions presented by Kern and her colleagues.

Think-Pair-Share Question

Modeling Enzyme Mechanism Esterases, enzymes capable of hydrolyzing esters into the carboxylic acid and alcohol components, are common in the circulatory system and in many tissues. Acetylsalicylic acid (Aspirin) undergoes ester hydrolysis by esterases when absorbed into circulation, releasing salicylic acid. The figure shows a model of an esterase with a simple diagram of its active site and the presence of three critical amino acid residues. Included in the figure are the structures of three possible substrates for this enzyme and their K_M values.

- a. Sketch a general enzyme mechanism for the hydrolysis of the ester bond in any of the three structures shown that involves (1) a transient covalent bond between substrate and enzyme and (2) a general base mechanism. (Use any relevant figure from Chapter 14 as your guide).
- b. Explain the differences in K_M values.

Enzyme Regulation

15

Christie's Images/Corbis

Allostery is a key chemical process that makes possible intracellular and intercellular regulation: "... the molecular interactions which ensure the transmission and interpretation of (regulatory) signals rest upon (allosteric) proteins endowed with discriminatory stereospecific recognition properties."

Jacques Monod
Chance and Necessity

◀ Like the delicate balance of forces in this mobile, metabolic regulation is achieved through a responsive interplay between enzymes and small molecules.

Essential Question

Regulation of enzyme activity ensures the harmonious integration of the diverse and often divergent reactions of metabolism. At key positions in metabolic pathways, regulatory enzymes sense the momentary needs of the cell and adjust their catalytic activity accordingly. **What are the properties of regulated enzymes? How do regulatory enzymes sense the momentary needs of cells? What molecular mechanisms are used to regulate enzyme activity?**

Enzymes catalyze essentially all of the thousands of metabolic reactions taking place in cells. Many of these reactions are at cross-purposes: Some enzymes catalyze the breakdown of substances, whereas others catalyze synthesis of the same substances; many metabolic intermediates have more than one fate; and energy is released in some reactions and consumed in others.

15.1 | What Factors Influence Enzymatic Activity?

The activity displayed by enzymes is affected by a variety of factors, some of which are essential to the harmony of metabolism. Two ways to regulate the amount of activity at a given time are (1) to increase or decrease the number of enzyme molecules and (2) to increase or decrease the activity of each enzyme molecule. Although these ways seem straightforward, the cellular mechanisms to achieve them are complex and varied.

Key Questions

- 15.1 What Factors Influence Enzymatic Activity?
- 15.2 What Are the General Features of Allosteric Regulation?
- 15.3 Can Allosteric Regulation Be Explained by Conformational Changes in Proteins?
- 15.4 What Kinds of Covalent Modification Regulate the Activity of Enzymes?

15.1a The Availability of Substrates and Cofactors Usually Determines How Fast the Reaction Goes

The availability of substrates and cofactors typically determines the enzymatic reaction rate. In general, enzymes have evolved such that their K_m values approximate the prevailing *in vivo* concentration of their substrates. (It is also true that the concentration of some enzymes in cells is within an order of magnitude or so of the concentrations of their substrates.)

15.1b As Product Accumulates, the Apparent Rate of the Enzymatic Reaction Will Decrease

The enzymatic rate, $v = d[P]/dt$, slows down as product accumulates and equilibrium is approached. The apparent decrease in rate is due to the conversion of P to S by the reverse reaction as [P] rises. Once $[P]/[S] = K_{eq}$, no further reaction is apparent. K_{eq} defines thermodynamic equilibrium. Enzymes have no influence on the thermodynamics of a reaction. Also, product inhibition can be a kinetically valid phenomenon: Some enzymes are inhibited by the products of their action.

15.1c Genetic Regulation of Enzyme Synthesis Determines the Amount of Enzyme Present at Any Moment

The amount of enzyme synthesized by a cell is determined by transcription regulation. If the gene encoding a particular enzyme protein is turned on or off, changes in the amount of enzyme activity soon follow. **Induction**, which is enzyme synthesis through transcriptional activation, and **repression**, which is the shutdown of enzyme synthesis, are important mechanisms for the regulation of metabolism. By controlling the amount of an enzyme that is present at any moment, cells can either activate or terminate various metabolic routes. Genetic controls over enzyme levels have a response time ranging from minutes in rapidly dividing bacteria to hours (or longer) in higher eukaryotes. Once synthesized, the enzyme may also be degraded, either through normal turnover of the protein or through specific decay mechanisms that target the enzyme for destruction.

15.1d Enzyme Activity Can Be Regulated Allosterically

Enzymatic activity can also be activated or inhibited through noncovalent interaction of the enzyme with small molecules (metabolites) other than the substrate. This form of control is termed **allosteric regulation** because the activator or inhibitor binds to the enzyme at a site *other* than (*allo* means “other”) the active site. Furthermore, such allosteric regulators, or **effector molecules**, are often quite different sterically from the substrate. Because this form of regulation results simply from reversible binding of regulatory ligands to the enzyme, the cellular response time can be virtually instantaneous.

Careers in Chemistry

Dr. Ciarra Smith

Dr. Ciarra Smith is the Manager of Diversity, Equity and Inclusion (DEI) Programs for the American Society for Biochemistry and Molecular Biology. Her work for the ASBMB includes managing DEI programs and initiatives that support and encourages opportunities for scientists from historically excluded backgrounds. Dr. Smith earned a BS in biology from the North Carolina Agricultural and Technical State University and a PhD from the Morningside Graduate School of Biomedical Sciences at the University of Massachusetts Chan Medical School. While a graduate student, Dr. Smith organized DEI

programs centered on the intersection of personal identity and science. As a postdoctoral associate at UMass, she organized inclusive teaching workshops, research seminars that highlighted diverse scientists, and a program for recruiting students from historically black colleges and universities. Dr. Smith's science background supports her work as she knows the struggles scientists go through. She also knows the holes in academia that need to be addressed when it comes to diversity, equity, accessibility, and inclusion, which is her passion.

Figure 15.1 Enzyme regulation by reversible covalent modification. Protein kinases catalyze the ATP-dependent phosphorylation of target proteins. Phosphoprotein phosphatases reverse this action by hydrolytic removal of the phosphate group.

15.1e Enzyme Activity Can Be Regulated through Covalent Modification

Enzymes can be regulated by **covalent modification**, the reversible covalent attachment of a chemical group. Enzymes susceptible to such regulation are called **interconvertible enzymes** because they can be reversibly converted between two forms. Thus, a fully active enzyme can be converted into an inactive form simply by the covalent attachment of a functional group. Covalent modification reactions are catalyzed by special **converter enzymes**, which are themselves subject to metabolic regulation. **Protein kinases** are one class of converter enzymes. They act in covalent modification by attaching a phosphoryl moiety to target proteins (Figure 15.1). Protein kinases catalyze the ATP-dependent phosphorylation of —OH groups on Ser, Thr, or Tyr side chains (or in some cases, the imidazole-N atoms in histidine residues). Removal of the phosphate group by a **phosphoprotein phosphatase** returns the enzyme to its original state. In contrast to the example in Figure 15.1, some enzymes exist in an inactive state unless specifically converted into the active form through covalent addition of a functional group. Although covalent modification represents a stable alteration of the enzyme, a different converter enzyme operates to remove the modification. Thus, when the conditions that favored modification of the enzyme are no longer present, the process can be reversed, restoring the enzyme to its unmodified state. Because covalent modification events are catalyzed by enzymes, they occur very quickly, with response times of seconds or even less for significant changes in metabolic activity.

Enzyme regulation is an important matter to cells, and evolution has provided a variety of additional options, including zymogens, isozymes, and modulator proteins. We will discuss these options first and then return to the major topics of this chapter—enzyme regulation through allosteric mechanisms and covalent modification.

15.1f Zymogens Are Inactive Precursors of Enzymes

Most proteins become fully active as their synthesis is completed and they spontaneously fold into their native, three-dimensional conformations. Some proteins, however, are synthesized as inactive precursors, called **zymogens** or **proenzymes**, that acquire full activity only upon specific proteolytic cleavage of one or several of their peptide bonds. Unlike allosteric regulation or covalent modification, zymogen activation by specific proteolysis is an irreversible process. Activation of enzymes and other physiologically important proteins by specific proteolysis is a strategy frequently exploited by biological systems to switch on processes at the appropriate time and place, as the following examples illustrate.

Insulin Some protein hormones are synthesized in the form of inactive precursor molecules, from which the active hormone is derived by proteolysis. For instance, **insulin**, an important metabolic regulator, is generated by proteolytic excision of a specific peptide from **proinsulin** (Figure 15.2).

Proteolytic Enzymes of the Digestive Tract Enzymes of the digestive tract that serve to hydrolyze dietary proteins are synthesized in the stomach and pancreas as zymogens (Table 15.1). Only upon proteolytic activation are these enzymes able to form a catalytically active substrate-binding site. The activation of chymotrypsinogen is an interesting example (Figure 15.3). **Chymotrypsinogen** is a 245 residue polypeptide chain crosslinked by five disulfide bonds. Chymotrypsinogen is converted to an enzymatically active form called π -chymotrypsin when trypsin cleaves the peptide bond joining Arg¹⁵ and Ile¹⁶. The enzymatically active π -chymotrypsin acts upon other

Figure 15.2 Proinsulin is an 86 residue precursor to insulin (the sequence shown here is human proinsulin). Proteolytic removal of residues 31 to 65 yields insulin. Residues 1 through 30 (the B chain) remain linked to residues 66 through 87 (the A chain) by a pair of interchain disulfide bridges.

Table 15.1 Pancreatic and Gastric Zymogens		
Zymogen	Active Protease	Origin
Trypsinogen	Trypsin	Pancreas
Chymotrypsinogen	Chymotrypsin	Pancreas

Proelastase	Elastase	Pancreas
Pepsinogen	Pepsin	Stomach

Figure 15.3 The proteolytic activation of chymotrypsinogen. Disulfide bonds are shown in yellow.

π -chymotrypsin molecules, excising two dipeptides: Ser¹⁴–Arg¹⁵ and Thr¹⁴⁷–Asn¹⁴⁸. The end product of this processing pathway is the mature protease **α -chymotrypsin**, in which the three peptide chains, A (residues 1 through 13), B (residues 16 through 146), and C (residues 149 through 245), remain together because they are linked by two disulfide bonds, one from A to B and one from B to C.

Blood Clotting The formation of blood clots is the result of a series of zymogen activations (Figure 15.4). The amplification achieved by this cascade of enzymatic activations allows blood clotting to occur rapidly in response to injury. Seven of the clotting factors in their active form are serine proteases: **kallikrein**, **XII_a**, **XI_a**, **IX_a**, **VII_a**, **X_a**, and **thrombin**. Two routes to blood clot formation exist. The **intrinsic pathway** is instigated when the blood contacts abnormal surfaces caused by injury; the **extrinsic pathway** is initiated by factors released from injured tissues. The pathways merge at factor X and culminate in clot formation. Thrombin excises peptides rich in negative charge from **fibrinogen**, converting it to **fibrin**, a molecule with a different surface charge distribution. Fibrin readily aggregates into ordered fibrous arrays that are subsequently stabilized by covalent crosslinks. Thrombin specifically cleaves Arg–Gly peptide bonds and is homologous to trypsin, which is also a serine protease.

15.1g
Isozymes Are Enzymes with Slightly Different Subunits and Kinetic Properties

A number of enzymes exist in more than one quaternary form, differing in their relative proportions of structurally equivalent but catalytically distinct polypeptide subunits. A classic example is mammalian **lactate dehydrogenase (LDH)**, which exists in two prominent oligomeric forms, M and H. LDH M is an A₄ homotetramer (the A subunit is encoded by the LDH A gene). LDH H is also a homotetramer, but its subunits are products of the LDH B gene, so its subunit composition is B₄ (Figure 15.5).

Figure 15.4 The cascade of activation steps leading to blood clotting. The intrinsic and extrinsic pathways converge at factor X, and the final common pathway involves the activation of thrombin and its conversion of fibrinogen into fibrin, which aggregates into ordered filamentous arrays that become crosslinked to form the clot.

Figure 15.5 The isozymes of lactate dehydrogenase (LDH). (a) The five possible A and B subunit distributions in LDH molecules. (b) Tissue distributions of the five LDH isomer types. Active skeletal muscle tissue becomes anaerobic and produces pyruvate from glucose via glycolysis. It needs LDH to regenerate NAD⁺ from NADH so that glycolysis can continue. The lactate produced is released into the blood. LDH M works best in the pyruvate-to-lactate direction. Heart tissue is aerobic and uses lactate as a fuel, converting it to pyruvate via LDH and using the pyruvate to fuel the citric acid cycle to obtain energy. LDH H works best in the lactate-to-pyruvate direction.

Heterotetrameric isozymes (A_3B , A_2B_2 , AB_3) can also form, depending on the relative expression of the LDH A and LDH B genes in different tissues. The kinetic properties of the various LDH isozymes differ. Different tissues express different isozyme forms, as appropriate to their particular metabolic needs. By regulating the relative amounts of A and B subunits they synthesize, the cells of various tissues control which isozymic forms are likely to assemble and thus which kinetic parameters prevail.

15.2 What Are the General Features of Allosteric Regulation?

The two prominent mechanisms of enzyme regulation that ensure rapid responses to meet the moment-by-moment metabolic needs of cells are allosteric regulation and covalent modification. Allosteric regulation acts to modulate enzymes situated at key steps in metabolic pathways. Consider as an illustration the following pathway, where A is the precursor for formation of an end product, F, in a sequence of five enzyme-catalyzed reactions:

In this scheme, F symbolizes an essential metabolite, such as an amino acid or a nucleotide. In such systems, F, the essential end product, inhibits *enzyme 1*, the *first step* in the pathway. Therefore, when sufficient F is synthesized, it blocks further synthesis of itself. This phenomenon is called **feedback inhibition** or **feedback regulation**.

15.2a Regulatory Enzymes Have Certain Exceptional Properties

Enzymes such as enzyme 1, which are subject to feedback regulation, represent a distinct class of enzymes, the **regulatory enzymes** (also called **allosteric enzymes**). As a class, these enzymes have certain exceptional properties:

1. Their kinetics do not obey the Michaelis–Menten equation. Their v versus $[S]$ plots yield **sigmoid- or S-shaped** curves rather than rectangular hyperbolas (Figure 15.6). Such curves suggest a second-order (or higher) relationship between v and $[S]$; that is, v is proportional to $[S]^n$, where $n > 1$. A qualitative description of the mechanism responsible for the S-shaped curves is that binding of one S to a protein molecule makes it easier for additional substrate molecules to bind to the same protein molecule. In the jargon of allostery, substrate binding is **cooperative**.
2. Inhibition of a regulatory enzyme by a feedback inhibitor does not conform to any normal inhibition pattern, and the feedback inhibitor F bears little structural similarity to A, the substrate for the regulatory enzyme. F apparently acts at a binding site distinct from the substrate-binding site. The term *allosteric* is apt, because F is sterically dissimilar and, moreover, acts at a site other than the site for S. Its effect is called **allosteric inhibition**.
3. Regulatory or allosteric enzymes like enzyme 1 are, in some instances, regulated by activation. That is, whereas some effector molecules such as F exert negative effects on enzyme activity, other effectors show stimulatory, or positive, influences on activity.
4. Allosteric enzymes typically have an oligomeric organization. They are composed of more than one polypeptide chain (subunit), and each subunit has a binding site for substrate, as well as a distinct binding site for allosteric effectors. Thus, allosteric enzymes typically have more than one S-binding site and more than one effector-binding site per enzyme molecule.
5. The interaction of an allosteric enzyme with effectors alters the distribution of conformational possibilities or subunit interactions available to the enzyme. That is, the regulatory effects exerted on the enzyme's activity are achieved by conformational changes occurring in the protein when effector metabolites bind.

The exponent n is referred to as the Hill coefficient, in honor of Archibald V. Hill, who first observed sigmoid binding curves in studies of O_2 binding by hemoglobin.

Figure 15.6 Sigmoid v versus $[S]$ plot. The blue line represents the hyperbolic plot characteristic of normal Michaelis–Menten-type enzyme kinetics. The red line is S-shaped or sigmoid, and v is proportional to $[S]^n$, where $n > 1$. As lines with ever greater values of n are drawn, the resulting v vs. $[S]$ curves approach a step function (the curves more and more resemble a step from zero v to $V_{\max}$ over a very narrow range of $[S]$). As n increases, the response of v to S binding is described as being more cooperative; that is, the system is showing ultrasensitivity: v is very sensitive to $[S]$ over a narrow range of $[S]$.

In addition to enzymes, noncatalytic proteins may exhibit many of these properties; hemoglobin is the classic example. The allosteric properties of hemoglobin are the subject of Section 15.6 What Is the Relationship Between Quaternary Structure and Allosteric Regulation?

15.3 | Can Allosteric Regulation Be Explained by Conformational Changes in Proteins?

Conformational changes lie at the heart of protein function and allosteric regulation is no exception. Various models have been proposed to account for the behavior of allosteric proteins. All of them note that proteins can exist in different conformational states. Models usually propose a small number of conformations (two or, at most, three) for a given protein.

15.3a The Symmetry Model for Allosteric Regulation Is Based on Two Conformational States for a Protein

For example, the model for allosteric behavior of Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux (**the MWC model**) proposes two conformational states for an allosteric protein: the **R (relaxed) state** and the **T (taut) state**. The MWC model is sometimes referred to as the **symmetry model** because all subunits in an oligomer are assumed to have the same conformation, whether it is R or T. R-state and T-state protein molecules are in equilibrium, with the T conformation greatly favored over the R ($[T] \gg [R]$), under conditions in which no ligands are present. Assume the substrate S binds only to R, with A (the activator) and I (the inhibitor) binding to R and T, respectively. The linked equilibria lead to changes in the relative amounts of R and T and, therefore, shifts in the substrate saturation curve. The parameters of such a system are that (1) S and A (or I) have different affinities for R and T and (2) A (or I) modifies the apparent $K_{0.5}$ for S by shifting the relative R versus T population. This model further suggests that substrate and allosteric activators (positive effectors) bind only to the R state and allosteric inhibitors (negative effectors) bind only to the T state. Figure 15.7 illustrates such a model for a dimeric protein, each monomer of which has a substrate-binding site and an effector-binding site. Because S binds only to the R state, S binding perturbs the $R \rightleftharpoons T$ equilibrium in favor of more R-state conformers and thus more S binding. That is, S binding is cooperative. The concentration of ligand giving half-maximal response is defined as $K_{0.5}$. (Like K_m , the units of $K_{0.5}$ are molarity; K_m cannot be used to describe these constants because the protein does not conform to the Michaelis–Menten model for enzyme kinetics.) The MWC model accounts for the action of allosteric effectors. Positive effectors bind only to the R state and thus cause a shift of the $R \rightleftharpoons T$ equilibrium in favor of more R and thus easier S binding. Negative effectors do the opposite; they perturb the $R \rightleftharpoons T$ equilibrium in favor of T, the conformation that cannot bind S. Note that positive effectors (allosteric activators) cause a decline in the $K_{0.5}$ for S (signifying easier binding of S) and negative effectors raise $K_{0.5}$ for S (Figure 15.7). Note that the MWC model assumes an equilibrium between conformational states, but ligand binding does not alter the conformation of the protein.

15.3b The Sequential Model for Allosteric Regulation Is Based on Ligand-Induced Conformational Changes

An alternative model proposed by Daniel Koshland, George Nemethy, and David Filmer (**the KNF model**) relies on the well-accepted idea that ligand binding triggers a change in the conformation of a protein. And, if the protein is oligomeric, ligand-induced conformational changes in one subunit may lead to changes in the conformation of its neighbors. Such ligand-induced conformational change could cause the subunits of an oligomeric protein to shift from a low-affinity state to a high-affinity state. For example, S binding to one monomer may cause the other monomers to adopt conformations with higher affinity for S (Figure 15.8). Interestingly, the KNF

Figure 15.7 The MWC symmetry model for allosteric behavior (a) The allosteric protein exists in two conformational states, R (pink) and T (orange). Assume S binds only to R, with A and I binding to R and T, respectively. The linked equilibria lead to changes in the relative amounts of R and T and, therefore, shifts in the substrate saturation curve. (b) The parameters of such a system are that (1) S and A (or I) have different affinities for R and T and (2) A (or I) modifies the apparent $K_{0.5}$ for S by shifting the relative R versus T population.

(a) Binding of S induces a conformational change.

If the relative affinities of the various conformations for S are

(d)

Figure 15.8 The Koshland–Nemethy–Filmer sequential model for allosteric behavior. (a) S binding can, by induced fit, cause a conformational change in the subunit to which it binds. (b) If subunit interactions are tightly coupled, binding of S to one subunit may cause the other subunit to assume a conformation having a greater or lesser affinity for S. That is, the ligand-induced conformational change in one subunit can affect the adjoining subunit. (c) Such effects could be transmitted between neighboring peptide domains by changing alignments of nonbonded amino acid residues. (d) Theoretical curves for the binding of a ligand to a protein having four identical subunits, each with one binding site for the ligand. The fraction of maximal velocity ($v/V_{\max}$) is plotted as a function of $[S]/K_{0.5}$.

model also explains how ligand-induced conformational changes could cause subunits of a protein to adopt conformations with little or no affinity for the ligand, a phenomenon referred to as **negative cooperativity**. The KNF model is termed the **sequential model** because subunits undergo sequential changes in conformation due to ligand binding. A comparison of the response of velocity to substrate concentration for positive versus negative cooperativity is shown in Figure 15.8d.

15.3c The Notable Difference between the MWC and KNF Models

In the MWC model, the different conformations have different affinities for the various ligands, and the concept of ligand-induced conformational changes is ignored. In contrast, the KNF model is based on ligand-induced conformational changes.

15.3d Changes in the Oligomeric State of a Protein Can Also Give Allosteric Behavior

Although the MWC and KNF models are the best-known paradigms for allosteric protein behavior, other models have been put forward. For example, instead of R and T, consider a monomer–oligomer equilibrium for an allosteric protein, where only the oligomer binds S and [monomer] $\gg$ [oligomer]. This model strongly resembles the MWC model. In yet another model, we might have a monomeric protein with distinct binding sites for several different ligands. In this case, binding of ligand A to its site might cause a conformational change such that the protein shows much greater affinity for S than it would in the absence of A. Or, binding of ligand I might result in a conformational change in the protein such that its affinity for S is abolished. Although the binding of other ligands may affect the affinity of the monomer for S, S binding cannot show cooperativity in monomeric proteins, because, unlike oligomers, the monomer has only one binding site for S.

It is important to realize that all of these various models are attempts to use simple concepts to explain the complex behavior of a protein. Although these models provide reasonable approximations and useful insights, the molecular mechanisms underlying allostery cannot be expected to conform rigidly to any one of these models. Shortly, we explore the regulated behavior of a real protein (glycogen phosphorylase) with these models in mind.

15.4 | What Kinds of Covalent Modification Regulate the Activity of Enzymes?

Covalent modification of proteins through introduction of phosphoryl groups and/or other charged or bulky functional groups results in substantial protein conformational changes that can dramatically affect enzyme activity.

15.4a Covalent Modification through Reversible Phosphorylation

As we saw in Figure 15.1, enzyme activity can be regulated through reversible phosphorylation; indeed it is the most prominent form of covalent modification in cellular regulation. Phosphorylation is accomplished by protein kinases that target specific enzymes for modification. Phosphoprotein phosphatases operate in the reverse direction to remove the phosphate group through hydrolysis of the side-chain phosphoester bond. Because protein kinases and phosphoprotein phosphatases work in opposing directions, regulation must be imposed on these converter enzymes so that their interconvertible enzyme targets are locked in the desired state (active versus inactive) and a wasteful cycle of ATP hydrolysis is avoided. Thus, converter enzymes are themselves the targets of allosteric regulation or covalent modification.

15.4b Protein Kinases: Target Recognition and Intrasteric Control

Protein kinases are converter enzymes that catalyze the ATP-dependent phosphorylation of serine, threonine, or tyrosine hydroxyl groups in target proteins (Table 15.2). Phosphorylation introduces a bulky group bearing two negative charges, causing

Table 15.2 Examples of the Major Protein Kinase Classes According to Specificity, Consensus Target Sequence, and Activators		
Protein Kinase Class	Target Sequence*	Activators
I. Ser/Thr protein kinases		
A. Cyclic nucleotide-dependent cAMP-dependent (PKA) cGMP-dependent	—R(R/K)X(S*/T*)— —(R/K)KKX(S*/T*)—	cAMP cGMP
B. Ca ²⁺ -calmodulin (CaM)-dependent Phosphorylase kinase (PhK) Myosin light-chain kinase (MLCK)	—KRKQIS*VRGL— —KKRPQRATS*NV—	Phosphorylation by PKA Ca ²⁺ -CaM
C. Protein kinase C (PKC)		Ca ²⁺ , diacylglycerol
D. Mitogen-activated protein kinases (MAP kinases)	—PXX(S*/T*)P—	Phosphorylation by MAPK kinase
E. G-protein-coupled receptors β-Adrenergic receptor kinase (BARK) Rhodopsin kinase		
II. Ser/Thr/Tyr protein kinases		
MAP kinase kinase (MAPK kinase)	—TEY—	Phosphorylation by <i>Raf</i> (a protein kinase)
III. Tyr protein kinases		
A. Cytosolic tyrosine kinases (<i>src</i> , <i>fgr</i> , <i>abl</i> , etc.)		
B. Receptor tyrosine kinases (RTKs) Plasma membrane receptors for hormones such as <i>epidermal growth factor</i> (EGF) or <i>platelet-derived growth factor</i> (PDGF)		

*X denotes any amino acid.

Figure 15.9 Protein kinase A is shown complexed with a pseudosubstrate peptide (orange). This complex also includes ATP (red) and two Mn²⁺ ions (yellow) bound at the active site (PDB id = 1ATP).

conformational changes that alter the target protein’s function. The added phospho-ryl group is distinct from naturally occurring amino acids, since no amino acid side chain can provide two negative charges. Protein kinases represent a protein super-family whose members are widely diverse in terms of size, subunit structure, and subcellular localization. Nevertheless, all share a common catalytic mechanism based on a conserved catalytic core/kinase domain of approximately 260 amino acid resi-dues (Figure 15.9). Protein kinases are classified as Ser/Thr and/or Tyr specific. They also differ in terms of the target proteins that they recognize and phosphorylate; tar-get selection depends on the presence of an amino acid sequence within the target protein that is recognized by the kinase. For example, cAMP-dependent protein kinase (**PKA**) phosphorylates proteins having Ser or Thr residues within an R(R/K) X(S*/T*) target consensus sequence (* denotes the residue that becomes phospho-rylated). That is, PKA phosphorylates Ser or Thr residues that occur in an Arg-(Arg or Lys)-(any amino acid)-(Ser or Thr) sequence segment (Table 15.2). Although target sites for phosphorylation were originally defined as linear sequences of contiguous amino acids, it is now appreciated that residues that are not adjacent in the primary structure of the protein can come into proximity upon protein folding to form a con-sensus target motif for a protein kinase.

Since protein kinases identify their targets through recognition of specific consensus sequences, these kinases can be inhibited by a mechanism called **intrasteric control** (Figure 15.10). Intrasteric control occurs when a regulatory subunit (or protein domain) has a **pseudosubstrate sequence** that mimics the target sequence but usually lacks an OH-bearing side chain at the right place. For example, the cAMP-binding RI regulatory subunits of PKA possess the pseudosubstrate sequence RRG*A*I, and this sequence binds to the active site of PKA catalytic subunits, blocking their activity. This pseudosubstrate sequence has an alanine residue (A*) where serine occurs in the PKA target sequence; Ala is sterically similar to serine but lacks a phosphorylatable OH group. (There are two isoforms of R subunits. The RII isoform has an RRVS*V pseudosubstrate sequence.) When PKA regulatory subunits bind cAMP, they undergo a conformational change and dissociate from the catalytic (C) subunits, and the active site of PKA is free to bind and phosphorylate its targets. In other protein kinases, the pseudosubstrate sequence involved in intrasteric control and the kinase domain are part of the same polypeptide chain. In these cases, binding of an allosteric effector (like cAMP) induces a conformational change in the protein that releases the pseudosubstrate sequence from the active site of the kinase domain.

Figure 15.10 Cyclic AMP-dependent protein kinase (also known as *PKA*) is a 170 kDa R₂C₂ tetramer in mammalian cells. (a) The two R (regulatory) subunits bind two equivalents of cAMP each ($K_D^{\text{cAMP}} \approx 30\text{--}300$ nM). cAMP binding releases the R subunits from the C (catalytic) subunits. The C subunits are enzymatically active as monomers. In the molecular graphic on the left, a C₂R₂ tetramer, the C subunits are pink; the R subunits, blue (PDB id = 3TNP). When [cAMP] is low, an R-subunit dimer binds to two copies of the C subunit, forming an inactive complex (left). Note the highlighted β4-β5 loops in the RIIβ subunits, which dock the C subunits by binding to their C-terminal tails. Docking to the R subunits forces the C subunits into a closed, inactive conformation. When [cAMP] rises, it binds to the R subunits, causing their conformation to change, which releases the C subunits as enzymatically active monomers (PDB id = 1J3H; the molecular graphic on the right). (b) diagram showing inactive R₂C₂ tetramer of left. In the presence of cAMP, R₂C₂ dissociates to give an R₂(cAMP)₄ complex and two catalytically active C subunits.

The abundance of many protein kinases in cells is an indication of the great importance of protein phosphorylation in cellular regulation. Over 500 protein kinase genes have been identified in the human genome. (In contrast, there are less than 200 phosphoprotein phosphatase genes in the human genome.) **Tyrosine kinases** (protein kinases that phosphorylate Tyr residues) occur only in multicellular organisms (yeast has no tyrosine kinases). Tyrosine kinases are components of signaling pathways involved in cell-cell communication (see Chapter 32). Table 15.3 presents the classification of eukaryotic protein kinases genes into eight principal families according to function and conserved sequence similarity.

Table 15.3 Classification of Eukaryotic Protein Kinases According to Sequence Similarity*

Family	Family Members
AGC	This family of Ser-Thr kinases includes cAMP, cGMP, and Ca ²⁺ -phospholipid-dependent kinases; ribosomal protein S6-phosphorylating kinases; kinases that phosphorylate G protein-coupled receptors; and all close relatives of these groups.
CAMK	Ser-Thr kinases activated by Ca ²⁺ -calmodulin.
CK1	Ser-Thr kinases important in cell signaling and more; Casein kinase 1 and close relatives.
CMGC	Cyclin-dependent kinases, mitogen-activated protein kinases, CDK-like kinases, and glycogen synthase kinase. Members of this family may phosphorylate Ser, Thr, or Tyr residues.
RGC	Receptor guanylate cyclase kinases. These membrane receptors form cGMP from GTP. They are pseudo-kinases that have a domain sequence organization similar to TKs.
STE	Ser-Thr kinases functioning in MAP kinase cascades by phosphorylating MAP kinases.
TK	Tyrosine kinases phosphorylate Tyr residues; TKs include the growth factor receptor tyrosine kinases (RTKs).
TKL	Tyrosine kinase-like: a diverse family that resembles TKs, but are actually Ser-Thr kinases.

*This classification does not include atypical protein kinases (aPKs) because aPKs share no clear sequence similarity to any of these families. As such, aPKs are represented by only a small number of eukaryotic protein kinases.

15.4c Phosphorylation Is Not the Only Form of Covalent Modification That Regulates Enzyme Function

Several hundred different chemical modifications of proteins have been discovered thus far, ranging from carboxylation (addition of a carboxyl group), acetylation (addition of an acetyl group), prenylation (see Figure 9.23), and glycosylation (see Figures 7.32 through 7.37), to covalent attachment of a polypeptide to the protein (addition of ubiquitin to free amino groups on proteins), to name just a few. A compilation of known protein modifications can be found in RESID, at <https://proteininformationresource.org/resid/resid.shtml> Only a small number of these covalent modifications are used to achieve metabolic regulation through reversible conversion of an enzyme between active and inactive forms. Table 15.4 presents a few examples. Note that three of these types of covalent modification require nucleoside triphosphates (ATP, UTP) that are related to cellular energy status; another relies on reducing potential within the cell, which also reflects cellular energy status.

15.4d Acetylation Is a Prominent Modification for the Regulation of Metabolic Enzymes

Acetylation of an $\epsilon\text{-NH}_3^+$ group on a lysine side chain changes it from a positively charged amino group to a neutral amide, which affects the protein's conformation and thus its function. The enzymes responsible are **acetyl-CoA-dependent lysine acetyltransferases** or **KATs**. Proteomics studies show that acetylation of metabolic enzymes is an important mechanism for regulating the flow of metabolic substrates (carbohydrates, fats) through the central metabolic pathways of carbohydrate and fat metabolism. Acetylation activates some enzymes and inhibits others. Cellular levels of major metabolic fuels such as glucose, fatty acids, and amino acids influence the degree of acetylation (Figure 15.11). The in vivo stability of some enzymes may also be

Table 15.4 Additional Examples of Regulation by Covalent Modification		
Reaction	Amino Acid Side Chain	Reaction (see figure indicated)
Adenylylation	Tyrosine	Transfer of AMP from ATP to Tyr-OH
Uridylylation	Tyrosine	Transfer of UMP from UTP to Tyr-OH
ADP-ribosylation	Arginine	Transfer of ADP-ribose from NAD ⁺ to Arg
Methylation	Glutamate	Transfer of methyl group from S-adenosylmethionine to Glu γ -carboxyl group
Oxidation–reduction	Cysteine (disulfide)	Reduction of Cys-S-S-Cys to Cys-SH + HS-Cys
Acetylation	Lysine	Transfer of acetyl group from acetyl-CoA to Lys ϵ -amino group

Figure 15.11 Activation of the tricarboxylic acid cycle enzyme, malate dehydrogenase (MDH) by acetylation. **(a)** Relative MDH activity from human liver cells in the absence (–) and presence (+) of inhibitors of lysine deacetylating enzymes. **(b)** Activation of MDH in human liver cells treated with glucose. The relative MDH activity in human liver cells exposed to a range (0, 6.25, 12.5, and 25 mM) of glucose concentrations is shown. Glucose enhances MDH acetylation. regulated by acetylation. Deacetylation by **KDACs (lysine deacetylases)** reverses the effects of acetylation. KDACs include *sirtuins*, a class of NAD^+ -dependent protein deacetylating enzymes. Sirtuins are implicated in the regulation of energy metabolism and longevity.

15.5 | Is the Activity of Some Enzymes Controlled by Both Allosteric Regulation and Covalent Modification?

Many allosteric enzymes are also subject to regulation by covalent modification. As a general rule, the covalently modified allosteric enzyme is more active and less responsive to allosteric regulation. Exceptions to this rule are allosteric enzymes that are less active and more responsive to allosteric regulation when they are covalently modified. Glycogen phosphorylase, the enzyme that catalyzes the release of glucose units from glycogen, serves as an excellent example of the many enzymes regulated both by allosteric controls and by covalent modification.

15.5a The Glycogen Phosphorylase Reaction Converts Glycogen into Readily Usable Fuel in the Form of Glucose-1-Phosphate

The cleavage of glucose units from the nonreducing ends of glycogen molecules is catalyzed by **glycogen phosphorylase**, an allosteric enzyme. The enzymatic reaction involves phosphorolysis of the bond between C-1 of the glucose unit and the glycosidic oxygen, to yield *glucose-1-phosphate* and a glycogen molecule that is shortened by one residue (Figure 15.12). (Because the reaction involves attack by phosphate instead of H_2O , it is referred to as **phosphorolysis** rather than hydrolysis.) Phosphorolysis produces a phosphorylated sugar product, glucose-1-P, which is converted to the glycolytic substrate, glucose-6-P, by *phosphoglucomutase* (Figure 15.13).

15.5b Glycogen Phosphorylase Is a Homodimer

Muscle glycogen phosphorylase is a dimer of two identical subunits (842 residues, 97 kDa). Each subunit contains an active site at the center of the subunit and an allosteric effector site near the subunit interface (Figure 15.14). In addition, a

Figure 15.12 The glycogen phosphorylase reaction.

Figure 15.13 The phosphoglucomutase reaction.

Figure 15.14 Structure of the glycogen phosphorylase monomer (PDB id = 8GPB).

regulatory phosphorylation site is located at Ser¹⁴ on each subunit. A glycogen-binding site on each subunit facilitates prior association of glycogen phosphorylase with its substrate and also exerts regulatory control on the enzymatic reaction.

Each subunit contributes a tower helix (residues 262 to 278) to the subunit–subunit contact interface in glycogen phosphorylase. In the phosphorylase dimer, the tower helices extend from their respective subunits and pack against each other in an antiparallel manner.

15.5c Glycogen Phosphorylase Activity Is Regulated Allosterically

The binding of the substrate *inorganic phosphate* (P_i) to muscle glycogen phosphorylase is highly cooperative (Figure 15.15a), which allows the enzyme activity to increase markedly over a rather narrow range of substrate concentration. That is, muscle glycogen phosphorylase shows cooperativity in substrate binding.

ATP and Glucose-6-P Are Allosteric Inhibitors of Glycogen Phosphorylase ATP can be viewed as the end product of glycogen phosphorylase action, in that the glucose-1-P liberated by glycogen phosphorylase is degraded in muscle via metabolic pathways whose purpose is energy (ATP) production. Glucose-1-P is readily converted into

Figure 15.15 v versus S curves for glycogen phosphorylase. **(a)** The response to the concentration of the substrate phosphate (P_i). **(b)** ATP and glucose-6-P are feedback inhibitors. **(c)** AMP is a positive effector. It binds at the same site as ATP.

glucose-6-P to feed such pathways. (In the liver, glucose-1-P from glycogen is converted to glucose and released into the bloodstream to raise blood glucose levels.) Thus, feedback inhibition of glycogen phosphorylase by ATP and glucose-6-P provides a very effective way to regulate glycogen breakdown. Both ATP and glucose-6-P act by decreasing the affinity of glycogen phosphorylase for its substrate P_i (Figure 15.15b). Because the binding of ATP or glucose-6-P has a negative effect on substrate binding, these substances act as *negative effectors*. Note in Figure 15.15b that the substrate saturation curve is displaced to the right in the presence of ATP or glucose-6-P, and a higher substrate concentration is needed to achieve half-maximal velocity ($V_{\max}/2$). When concentrations of ATP or glucose-6-P accumulate to high levels, glycogen phosphorylase is inhibited; when [ATP] and [glucose-6-P] are low, the activity of glycogen phosphorylase is regulated by availability of its substrate, P_i .

AMP Is an Allosteric Activator of Glycogen Phosphorylase AMP also provides a regulatory signal to glycogen phosphorylase. It binds to the same site as ATP, but it stimulates glycogen phosphorylase rather than inhibiting it (Figure 15.15c). AMP acts as a *positive effector*, meaning that it enhances the binding of substrate to glycogen phosphorylase. Significant levels of AMP indicate that the energy status of the cell is low and that more energy (ATP) should be produced. Reciprocal changes in the cellular concentrations of ATP and AMP and their competition for binding to the same site (the *allosteric site*) on glycogen phosphorylase, with opposite effects, allow these two nucleotides to exert *rapid and reversible control* over glycogen phosphorylase activity. Such reciprocal regulation ensures that the production of energy (ATP) is commensurate with cellular needs.

To summarize, muscle glycogen phosphorylase is allosterically activated by AMP and inhibited by ATP and glucose-6-P. When ATP and glucose-6-P are abundant, glycogen breakdown is inhibited. When cellular energy reserves are low (i.e., high [AMP] and low [ATP] and [G-6-P]), glycogen catabolism is stimulated. Caffeine can also act as an allosteric inhibitor of muscle glycogen phosphorylase (Figure 15.16).

Glycogen phosphorylase conforms to the MWC model of allosteric transitions, with the active form of the enzyme designated the R state and the inactive form denoted as the T state (Figure 15.16). Thus, AMP promotes the conversion to the active R state, whereas ATP, glucose-6-P, and caffeine favor conversion to the inactive T state.

Figure 15.16 The mechanism of covalent modification and allosteric regulation of glycogen phosphorylase. Covalent modification converts glycogen phosphorylase from the feedback-regulated, less active *b* form to the intrinsically more active *a* form that is unresponsive to feedback inhibition.

Figure 15.17 The major conformational change that occurs in the N-terminal residues upon phosphorylation of Ser¹⁴. Ser¹⁴ is shown in red. N-terminal conformation of unphosphorylated enzyme (phosphorylase *b*): yellow; N-terminal conformation of phosphorylated enzyme (phosphorylase *a*): cyan. (Molecular graphic created from PDB id = 8GPB and PDB id = 1GPA.)

X-ray diffraction studies of glycogen phosphorylase in the presence of allosteric effectors have revealed the molecular basis for the $T \rightleftharpoons R$ conversion. Although the structure of the central core of the phosphorylase subunits is identical in the T and R states, a significant change occurs at the subunit interface between the T and R states. This conformation change at the subunit interface is linked to a structural change at the active site that is important for catalysis. In the T state, the negatively charged carboxyl group of Asp²⁸³ faces the active site, so binding of the anionic substrate phosphate is unfavorable. In the conversion to the R state, Asp²⁸³ is displaced from the active site and replaced by Arg⁵⁶⁹. The exchange of negatively charged aspartate for positively charged arginine at the active site provides a favorable binding site for phosphate anion. These allosteric controls serve as a mechanism for adjusting the activity of glycogen phosphorylase to meet normal metabolic demands. However, in crisis situations in which abundant energy (ATP) is needed immediately, these controls can be overridden by covalent modification of glycogen phosphorylase. Covalent modification through phosphorylation of Ser¹⁴ in glycogen phosphorylase converts the enzyme from a less active, allosterically regulated form (the *b* form) to a more active, allosterically unresponsive form (the *a* form).

15.5d Covalent Modification of Glycogen Phosphorylase Overrides Allosteric Regulation

As early as 1938, it was known that glycogen phosphorylase existed in two forms: the less active **phosphorylase *b*** and the more active **phosphorylase *a***. In 1956 Edwin Krebs and Edmond Fischer reported that a converting enzyme could convert phosphorylase *b* to phosphorylase *a*. Three years later, Krebs and Fischer demonstrated that the conversion of phosphorylase *b* to phosphorylase *a* involved covalent phosphorylation, as shown in Figure 15.16.

Phosphorylation of Ser¹⁴ causes a dramatic conformation change in phosphorylase. Upon phosphorylation, the amino-terminal end of the protein (including residues 10 through 22) swings through an arc of 120°, moving into the subunit interface (Figure 15.17). This conformation change moves Ser¹⁴ by more than 3.6 nm. The phosphorylated, or *a* form, of glycogen phosphorylase is much less sensitive to allosteric regulation than the *b* form. Thus, covalent modification of glycogen phosphorylase converts this enzyme from an allosterically regulated form into a persistently active form. Covalent modification overrides the allosteric regulation.

Dephosphorylation of glycogen phosphorylase is carried out by **phosphoprotein phosphatase 1**. The action of phosphoprotein phosphatase 1 inactivates glycogen phosphorylase. The 1992 Nobel Prize in Physiology or Medicine was awarded to Krebs and Fischer for their pioneering studies of reversible protein phosphorylation as an important means of cellular regulation.

15.5e Enzyme Cascades Regulate Glycogen Phosphorylase Covalent Modification

The phosphorylation reaction that activates glycogen phosphorylase is mediated by an **enzyme cascade** (Figure 15.18). The first part of the cascade leads to hormonal stimulation (described in the next section) of **adenylyl cyclase**, a membrane-bound enzyme that converts ATP to *adenosine-3',5'-cyclic monophosphate*, denoted as *cyclic AMP* or simply *cAMP* (Figure 15.19). This regulatory molecule is found in all eukaryotic cells and acts as an intracellular messenger molecule, controlling a wide variety of processes. Cyclic AMP is known as a **second messenger** because it is the intracellular agent of a hormone (the first messenger).

The hormonal stimulation of adenylyl cyclase is effected by a transmembrane signaling pathway consisting of three components, all membrane associated. Binding of hormone to the external surface of a hormone receptor causes a conformational change in this transmembrane protein, which in turn stimulates a **GTP-binding protein** (abbreviated **G protein**). G proteins are heterotrimeric proteins consisting of α - (45–47 kDa), β - (35 kDa), and γ - (7–9 kDa) subunits. The α -subunit binds GDP or GTP and has an intrinsic, slow GTPase activity. In the inactive state, the $G_{\alpha\beta\gamma}$ complex has GDP at the nucleotide site.

Figure 15.18 The hormone-activated enzymatic cascade that leads to activation of glycogen phosphorylase.

Figure 15.19 The adenylyl cyclase reaction. The reaction is driven forward by subsequent hydrolysis of pyrophosphate by the enzyme inorganic pyrophosphatase.

When a G protein is stimulated by a hormone–receptor complex, GDP dissociates and GTP binds to G_α , causing it to dissociate from $G_{\beta\gamma}$ and to associate with adenylyl cyclase (Figure 15.20). Binding G_α (GTP) activates adenylyl cyclase to form cAMP from ATP. However, the intrinsic GTPase activity of G_α eventually hydrolyzes GTP to GDP, leading to dissociation of G_α (GDP) from adenylyl cyclase and reassociation with $G_{\beta\gamma}$ to form the inactive $G_{\alpha\beta\gamma}$ complex. This cascade amplifies the hormonal signal because a single hormone–receptor complex can activate many G proteins before the hormone dissociates from the receptor, and because the G_α -activated adenylyl cyclase can synthesize many cAMP molecules before bound GTP is hydrolyzed by G_α . Over 800 different human genes encoding G-protein coupled receptors (GPCRs) have been identified and more than 20 distinct G_α proteins are known. Since hormone-activated GPCRs catalyze GTP/GDP exchange on G proteins, they are sometimes called **guanine nucleotide exchange factors (GEFs)**. GPCRs are key components in a large number of eukaryotic signaling cascades.

Cyclic AMP is an essential activator of *cAMP-dependent protein kinase* (*PKA*). Binding of cyclic AMP to the regulatory subunits induces a conformation change that causes the dissociation of the C monomers from the R dimer (Figure 15.10). The free C subunits are active and can phosphorylate other proteins. One of the many proteins phosphorylated by PKA is *phosphorylase kinase* (Figure 15.18). Phosphorylase kinase is inactive in the unphosphorylated state and active in the phosphorylated form. As its name implies, phosphorylase kinase functions to phosphorylate (and activate) glycogen phosphorylase. Thus, hormonal activation of adenylyl cyclase leads to activation of glycogen breakdown.

Figure 15.20 Hormone binding to its receptor leads via G-protein activation to cAMP synthesis. Adenylyl cyclase and the hormone receptor are integral plasma membrane proteins; G_{α} and $G_{\beta\gamma}$ are membrane-anchored proteins.

15.6 What Is the Relationship between Quaternary Structure and Allosteric Regulation?

Allosteric regulation is a property of proteins that likely emerged with the appearance of quaternary structure. Many proteins that are not enzymes, such as hormone receptors, are allosterically regulated. As a monomer and a tetramer, **myoglobin (Mb)** and **hemoglobin (Hb)** provide insights the relationship between allostery and quaternary organization. This section focuses exclusively on the comparative biochemistry of Mb and Hb to reveal these insights. Myoglobin and hemoglobin are oxygen (O_2)-binding proteins found in animals. Mb serves as an O_2 -storage protein in muscle; Hb functions as an O_2 -transport protein in blood. Because they are two of the most-studied proteins in nature, they have become paradigms of protein structure and function. Moreover, hemoglobin is a model for protein quaternary structure and allosteric function. The binding of O_2 by hemoglobin, and its modulation by effectors such as protons, CO_2 , and 2,3-bisphosphoglycerate, depend on interactions between subunits in the Hb tetramer. Subunit–subunit interactions in Hb reveal much about the functional significance of quaternary associations and allosteric regulation.

15.6a The Comparative Biochemistry of Myoglobin and Hemoglobin Reveals Insights into Allostery

A comparison of the properties of hemoglobin and myoglobin offers insights into allosteric phenomena, even though these proteins are not enzymes. Hemoglobin displays sigmoid-shaped O_2 -binding curves (Figure 15.21). The unusual shape of these curves was once a great enigma in biochemistry. Such curves closely resemble allosteric enzyme–substrate saturation graphs (see Figure 15.6). In contrast, myoglobin's interaction with oxygen obeys classical Michaelis–Menten-type substrate saturation behavior.

Myoglobin is a compact globular protein composed of a single polypeptide chain 153 amino acids in length; its molecular mass is 17.2 kDa (Figure 15.22). It contains **heme**, a porphyrin ring system complexing an iron ion, as its prosthetic group (Figure 15.23). Oxygen binds to Mb via its heme. Hemoglobin (Hb) is also a compact globular protein, but Hb is a tetramer. It consists of four polypeptide chains, each of which is very similar structurally to the myoglobin polypeptide chain, and each bears a heme group. Thus, a hemoglobin molecule can bind four O_2 molecules. In adult human Hb, there are two identical chains of 141 amino acids, the α -chains, and two identical β -chains, each of 146 residues. The human Hb molecule is an $\alpha_2\beta_2$ -type tetramer of molecular mass 64.45 kDa.

The myoglobin polypeptide chain and the α - and β -chains of hemoglobin are composed of 8 α -helical segments denoted by the letters A through H. The short, unordered regions that connect the helices are named for the segments they connect, as in the AB

Figure 15.21 O_2 -binding curves for hemoglobin and myoglobin.

Figure 15.22 The myoglobin (PDB id = 2MM1) and hemoglobin (PDB id = 2HHB) molecules.

region or the EF region. In an amino acid numbering system unique to globin chains, successive residues in the helices are numbered, such as the histidine at position 8 in the F helix, known as His F8.

The tetrameric nature of Hb is crucial to its biological function: When a molecule of O_2 binds to a heme in Hb, the heme Fe ion is drawn into the plane of the porphyrin ring. This slight movement sets off a chain of conformational events that are transmitted to adjacent subunits, dramatically enhancing the affinity of their heme groups for O_2 . That is, the binding of O_2 to one heme of Hb makes it easier for the Hb molecule to bind additional equivalents of O_2 . Hemoglobin is a marvelously constructed molecular machine. Let us dissect its mechanism, beginning with its monomeric counterpart, the myoglobin molecule.

15.6b Myoglobin Is an Oxygen-Storage Protein

Myoglobin is the oxygen-storage protein of muscle. The muscles of diving mammals such as seals and whales are especially rich in this protein, which serves as a store for O_2 during the animal's prolonged periods underwater. Myoglobin is abundant in skeletal and cardiac muscle of nondiving animals as well. Myoglobin is the cause of the characteristic red color of muscle.

15.6c O_2 Binds to the Mb Heme Group

Iron prefers to interact with six ligands, four of which share a common plane. The fifth and sixth ligands lie above and below this plane (see Figure 15.24). In heme, four of the ligands are provided by the nitrogen atoms of the four pyrroles. A fifth ligand is donated by the imidazole side chain of amino acid residue His F8. When myoglobin binds O_2 to become **oxymyoglobin**, the O_2 molecule adds to the heme iron ion as the sixth ligand (Figure 15.24). O_2 adds end on to the heme iron, but it is not oriented perpendicular to the plane of the heme. Rather, it is tilted about 60° with respect to the perpendicular.

15.6d O_2 Binding Alters Mb Conformation

What happens when the heme group of myoglobin binds oxygen? X-ray crystallography has revealed that a crucial change occurs in the position of the iron atom relative to the plane of the heme. In deoxymyoglobin, the ferrous ion actually lies 0.055 nm above the plane of the heme, in the direction of His F8. The iron–porphyrin complex is therefore dome shaped. When O_2 binds, the iron atom is pulled back toward the porphyrin plane and is now displaced from it by only 0.026 nm. The consequences of this small motion are trivial as far as the biological role of myoglobin is concerned. However, as we shall soon see, this slight movement profoundly affects the properties of hemoglobin.

Figure 15.23 Heme is formed when protoporphyrin IX binds Fe^{2+} .

A Deeper Look

The Oxygen-Binding Curves of Myoglobin and Hemoglobin

Myoglobin

The reversible binding of oxygen to myoglobin,

can be characterized by the equilibrium dissociation constant, K .

$$K = \frac{[\text{Mb}][\text{O}_2]}{[\text{MbO}_2]} \quad (15.1)$$

If Y is defined as the **fractional saturation** of myoglobin with O_2 , that is, the fraction of myoglobin molecules having an oxygen molecule bound, then

$$Y = \frac{[\text{MbO}_2]}{[\text{MbO}_2] + [\text{Mb}]} \quad (15.2)$$

The value of Y ranges from 0 (no myoglobin molecules carry an O_2) to 1.0 (all myoglobin molecules have an O_2 molecule bound). Substituting from Equation 15.1, $([\text{Mb}][\text{O}_2])/K$ for $[\text{MbO}_2]$ gives

$$Y = \frac{\left(\frac{[\text{Mb}][\text{O}_2]}{K}\right)}{\left(\frac{[\text{Mb}][\text{O}_2]}{K} + [\text{Mb}]\right)} = \frac{\left(\frac{[\text{O}_2]}{K}\right)}{\left(\frac{[\text{O}_2]}{K} + 1\right)} = \frac{[\text{O}_2]}{[\text{O}_2] + K} \quad (15.3)$$

and, if the concentration of O_2 is expressed in terms of the partial pressure (in torr) of oxygen gas in equilibrium with the solution of interest, then

$$Y = \frac{p\text{O}_2}{p\text{O}_2 + K} \quad (15.4)$$

(In this form, K has the units of torr.) The relationship defined by Equation 15.4 plots as a hyperbola. That is, the MbO_2 saturation curve resembles an enzyme-substrate saturation curve. For myoglobin, a partial pressure of 1 torr for $p\text{O}_2$ is sufficient for half-saturation (Figure 1). We can define P_{50} as the partial pressure of O_2 at which 50% of the myoglobin molecules have a molecule of O_2 bound (that is, $Y = 0.5$), then

$$0.5 = \frac{p\text{O}_2}{p\text{O}_2 + P_{50}} \quad (15.5)$$

Figure 1 Oxygen saturation curve for myoglobin in the form of Y versus $p\text{O}_2$ showing P_{50} is at a $p\text{O}_2$ of 1 torr.

(Note from Equation 15.1 that when $[\text{MbO}_2] = [\text{Mb}]$, $K = [\text{O}_2]$, which is the same as saying when $Y = 0.5$, $K = P_{50}$.) The general equation for O_2 binding to Mb becomes

$$Y = \frac{p\text{O}_2}{p\text{O}_2 + P_{50}} \quad (15.6)$$

The ratio of the fractional saturation of myoglobin, Y , to free myoglobin, $1 - Y$, depends on $p\text{O}_2$ and K according to the equation

$$\frac{Y}{1 - Y} = \frac{p\text{O}_2}{K} \quad (15.7)$$

Hemoglobin

New properties emerge when four heme-containing polypeptides come together to form a tetramer. The O_2 -binding curve of hemoglobin is sigmoid rather than hyperbolic (see Figure 15.21), and Equation 15.4 does not describe such curves. Of course, each hemoglobin molecule has four hemes and can bind up to four oxygen molecules. Suppose for the moment that O_2 binding to hemoglobin is an all-or-none phenomenon, where Hb exists either free of O_2 or with four O_2 molecules bound. This supposition represents the extreme case for cooperative binding of a ligand by a protein with multiple binding sites. In effect, it says that if one ligand binds to the protein molecule, then all other sites are immediately occupied by ligand. Or, to say it another way for the case in hand, suppose that four O_2 molecules bind to Hb simultaneously:

Then the dissociation constant, K , would be

$$K = \frac{[\text{Hb}][\text{O}_2]^4}{[\text{Hb}(\text{O}_2)_4]} \quad (15.8)$$

By analogy with Equation 15.4, the equation for fractional saturation of Hb is given by

$$Y = \frac{[p\text{O}_2]^4}{[p\text{O}_2]^4 + K} \quad (15.9)$$

A plot of Y versus $p\text{O}_2$ according to Equation 15.9 is presented in Figure 2. This curve has the characteristic sigmoid shape seen for O_2 binding by Hb. Half-saturation is set to be a $p\text{O}_2$ of 26 torr. Note that when $p\text{O}_2$ is low, the fractional saturation, Y , changes very little as $p\text{O}_2$ increases. The interpretation is that Hb has little affinity for O_2 at these low partial pressures of O_2 . However, as $p\text{O}_2$ reaches some threshold value and the first O_2 is bound, Y , the fractional saturation, increases rapidly. Note that the slope of the curve is steepest in the region where $Y = 0.5$. The sigmoid character of this curve is diagnostic of the fact that the binding of O_2 to one site on Hb strongly enhances binding of additional O_2 molecules to the remaining vacant sites on the same Hb molecule, a phenomenon aptly termed **cooperativity**. (If each O_2 bound independently, exerting no influence on the affinity of Hb for more O_2 binding, this plot would be hyperbolic.)

The experimentally observed oxygen-binding curve for Hb does not fit the graph given in Figure 2 exactly. If we generalize Equation 15.9 by replacing the exponent 4 with n , we can write the equation as

$$Y = \frac{[p\text{O}_2]^n}{[p\text{O}_2]^n + K} \quad (15.10)$$

(Continued)

Rearranging yields

$$\frac{Y}{1 - Y} = \frac{[pO_2]^n}{K} \quad (15.11)$$

This equation states that the ratio of oxygenated heme groups (Y) to O_2 -free heme ($1 - Y$) is equal to the n th power of the pO_2 divided by the apparent dissociation constant, K .

Archibald Hill demonstrated in 1913, well before any knowledge about the molecular organization of Hb existed, that the O_2 -binding behavior of Hb could be described by Equation 15.11. If a value of 2.8 is taken for n , Equation 15.11 fits the experimentally

observed O_2 -binding curve for Hb very well (Figure 3). If the binding of O_2 to Hb were an all-or-none phenomenon, n would equal 4, as discussed previously. If the O_2 -binding sites on Hb were completely noninteracting, that is, if the binding of one O_2 to Hb had no influence on the binding of additional O_2 molecules to the same Hb, n would equal 1. Figure 3 compares these extremes. Obviously, the real situation falls between the extremes of $n = 1$ or 4. The qualitative answer is that O_2 binding by Hb is highly cooperative, and the binding of the first O_2 markedly enhances the binding of subsequent O_2 molecules. However, this binding is not quite an all-or-none phenomenon.

Figure 2 Oxygen saturation curve for Hb in the form of Y versus pO_2 , assuming $n = 4$ and $P_{50} = 26$ torr. The graph has the characteristic, experimentally observed, sigmoid shape.

Figure 3 A comparison of the experimentally observed O_2 curve for Hb yielding a value for n of 2.8 (blue), the hypothetical curve if $n = 4$ (red), and the curve if $n = 1$ (noninteracting O_2 -binding sites, purple).

15.6e Cooperative Binding of Oxygen by Hemoglobin Has Important Physiological Significance

The relative oxygen affinities of hemoglobin and myoglobin reflect their respective physiological roles (see Figure 15.21). Myoglobin, as an oxygen storage protein, has a greater affinity for O_2 than hemoglobin at all oxygen pressures. Hemoglobin, as the oxygen carrier, becomes saturated with O_2 in the lungs, where the partial pressure of O_2 (pO_2) is about 100 torr.¹ In the capillaries of tissues, pO_2 is typically 40 torr, and oxygen is released from Hb. In muscle, some of it can be bound by myoglobin, to be stored for use in times of severe oxygen deprivation, such as during strenuous exercise.

15.6f Hemoglobin Has an $\alpha_2\beta_2$ Tetrameric Structure

As noted, hemoglobin is an $\alpha_2\beta_2$ tetramer. Each of the four subunits has a conformation virtually identical to that of myoglobin (Figure 15.22). The subunits pack in a tetrahedral array, creating a roughly spherical molecule $6.4 \times 5.5 \times 5.0$ nm. The four heme groups, nestled within the easily recognizable cleft formed between the E and F helices of each polypeptide, are exposed at the surface of the molecule. The heme groups are quite far apart; 2.5 nm separates the closest iron ions, those of hemes α_1 and β_2 , and those of hemes α_2 and β_1 . The subunit interactions are mostly between dissimilar chains: Each of the α -chains is in contact with both β -chains, but there are few α - α or β - β interactions.

¹The **torr** is a unit of pressure named for Evangelista Torricelli, inventor of the barometer. One torr corresponds to 1 millimeter of mercury (1/760th of an atmosphere).

15.6g Oxygenation Markedly Alters the Quaternary Structure of Hb

X-ray crystallographic analysis reveals that oxyhemoglobin and deoxyhemoglobin differ markedly in quaternary structure. In particular, specific $\alpha\beta$ -subunit interactions change. Hemoglobin, as a conformationally dynamic molecule, consists of two dimeric halves, an $\alpha_1\beta_1$ -subunit pair and an $\alpha_2\beta_2$ -subunit pair. Each $\alpha\beta$ -dimer moves as a rigid body, and the two halves of the molecule slide past each other upon oxygenation of the heme. The two halves rotate some 15° about an imaginary pivot passing through the $\alpha\beta$ -subunits; some atoms at the interface between $\alpha\beta$ -dimers are relocated by as much as 0.6 nm.

15.6h Movement of the Heme Iron by Less Than 0.04 nm Induces the Conformational Change in Hemoglobin

In deoxyhemoglobin, histidine F8 is liganded to the heme iron ion, but steric constraints force the $\text{Fe}^{2+}\text{:His-N}$ bond to be tilted about 8° from the perpendicular to the plane of the heme. Steric repulsion between histidine F8 and the nitrogen atoms of the porphyrin ring system, combined with electrostatic repulsions between the electrons of Fe^{2+} and the porphyrin π -electrons, forces the iron atom to lie out of the porphyrin plane by about 0.06 nm. Changes in electronic and steric factors upon heme oxygenation allow the Fe^{2+} atom to move about 0.039 nm closer to the plane of the porphyrin, so now it is displaced only 0.021 nm above the plane. It is as if the O_2 were drawing the heme Fe^{2+} into the porphyrin plane (Figure 15.25). This modest displacement of 0.039 nm seems a trivial distance, but its biological consequences are far reaching. As the iron atom moves, it drags histidine F8 along with it, causing helix F, the EF corner, and the FG corner to follow. These shifts are transmitted to the subunit interfaces, where they trigger conformational readjustments that lead to the rupture of interchain salt links.

15.6i The Physiological Significance of the $\text{Hb}\text{:O}_2$ Interaction

We can determine quantitatively the physiological significance of the sigmoid nature of the hemoglobin oxygen-binding curve, or, in other words, the biological importance of cooperativity. The equation

$$\frac{Y}{1 - Y} = \frac{[p\text{O}_2]^n}{P_{50}}$$

describes the relationship between $p\text{O}_2$, the affinity of hemoglobin for O_2 (defined as P_{50} , the partial pressure of O_2 giving half-maximal saturation of Hb with O_2), and

Figure 15.25 Changes in the position of the heme iron atom upon oxygenation lead to conformational changes in the hemoglobin molecule. Darker shading shows the heme and F helix in the unoxygenated state and lighter shading shows the conformation of the heme and its movement of the F helix after O_2 -binding.

the fraction of hemoglobin with O_2 bound, Y , versus the fraction of Hb with no O_2 bound, $(1 - Y)$ (see A Deeper Look box: “The Oxygen-Binding Curves of Myoglobin and Hemoglobin”). The coefficient n is the Hill coefficient, an index of the cooperativity (sigmoidicity) of the hemoglobin oxygen-binding curve. Taking pO_2 in the lungs as 100 torr, P_{50} as 26 torr, and n as 2.8, the fractional saturation of the hemoglobin heme groups with O_2 , is 0.98. If pO_2 were to fall to 10 torr within the capillaries of an exercising muscle, Y would drop to 0.06. The oxygen delivered under these conditions would be proportional to the difference, $Y_{\text{lungs}} - Y_{\text{muscle}}$, which is 0.92. That is, virtually all the oxygen carried by Hb would be released. Suppose instead that hemoglobin binding of O_2 were not cooperative; in that case, the hemoglobin oxygen-binding curve would be hyperbolic, and $n = 1.0$. Then Y in the lungs would be 0.79 and Y in the capillaries, 0.28; the difference in Y values would be 0.51. Thus, under these conditions, the cooperativity of oxygen binding by Hb means that 0.92/0.51 or 1.8 times as much O_2 can be delivered.

15.6j The Oxy and Deoxy Forms of Hemoglobin Represent Two Different Conformational States

Hemoglobin resists oxygenation (see Figure 15.21) because the deoxy form is stabilized by specific hydrogen bonds and salt bridges (ion-pair bonds) (Figure 15.26). All of these interactions are broken in oxyhemoglobin, as the molecule stabilizes into a new conformation. The shift in helix F upon oxygenation leads to rupture of the Tyr β 145:Val β 98 hydrogen bond. In deoxyhemoglobin, with these interactions intact, the C-termini of the four subunits are restrained, and this conformational state is termed *T*, the *tense* or *taut form*. In oxyhemoglobin, these C-termini have almost complete freedom of rotation, and the molecule is now in its *R*, or *relaxed*, *form*.

15.6k The Allosteric Behavior of Hemoglobin Has Both Symmetry (MWC) Model and Sequential (KNF) Model Components

Oxygen is accessible only to the heme groups of the α -chains when hemoglobin is in the *T* conformational state. Max Perutz has pointed out that the heme environment of β -chains in the *T* state is virtually inaccessible because of steric hindrance by amino acid residues in the E helix. This hindrance disappears when the hemoglobin molecule undergoes transition to the *R* conformational state. Binding of O_2 to the β -chains is thus dependent on a *T*-to-*R* conformational shift, and this shift is triggered by the subtle changes that occur when O_2 binds to the α -chain heme groups. Together these observations describe a behavior that is partially MWC and partially KNF: O_2 binding to one α -subunit and then the other leads to sequential changes in conformation, followed by a switch in quaternary structure at the Hb: $2O_2$ state from *T* to *R*. Thus, the real behavior of this protein is an amalgam of the two prominent theoretical models for allosteric behavior.

15.6l H^+ Promotes the Dissociation of Oxygen from Hemoglobin

Protons, carbon dioxide, and chloride ions, as well as the metabolite 2,3-bisphosphoglycerate (or BPG), all affect the binding of O_2 by hemoglobin. Their effects have interesting ramifications, which we shall see as we discuss them in turn. Deoxyhemoglobin has a higher affinity for protons than oxyhemoglobin. Thus, as the pH decreases, dissociation of O_2 from hemoglobin is enhanced. In simple symbolism, ignoring the stoichiometry of O_2 or H^+ involved:

Expressed another way, H^+ is an antagonist of oxygen binding by Hb, and the saturation curve of Hb for O_2 is displaced to the right as acidity increases (Figure 15.27). This phenomenon is called the **Bohr effect**, after its discoverer, Danish physiologist Christian Bohr (the father of Niels Bohr, the atomic physicist). The effect has important physiological significance because actively metabolizing tissues produce acid, promoting O_2 release where it is most needed. About two protons are taken up by deoxyhemoglobin. The N-termini of the two α -chains and the His β 146 residues have

(a)

(b)

Figure 15.26 Salt bridges between different subunits in human deoxyhemoglobin. These noncovalent, electrostatic interactions are disrupted upon oxygenation. **(a)** A focus on those salt bridges and hydrogen bonds involving interactions between N-terminal and C-terminal residues in the α -chains. Residues in the lower center are Arg α_1 141 (green) with Val α_1 1 (purple), Asp α_2 126 (orange), Lys α_2 127 (yellow), and Val β_2 34 (olive); residues at top are Val α_1 93 (yellow) with Tyr α_1 140 (purple). **(b)** A focus on those salt bridges and hydrogen bonds involving C-terminal residues of β -chains: Val β_2 78 (olive) with Tyr β_2 145 (purple); His β_2 146 (light blue) with Asp β_2 94 (orange) and Lys α_1 40 (yellow) (PDB id = 2HHB).

Figure 15.27 The oxygen saturation curves for myoglobin and for hemoglobin at five different pH values: 7.6, 7.4, 7.2, 7.0, and 6.8.

Figure 15.28 Oxygen-binding curves of blood and of hemoglobin in the absence and presence of CO_2 and BPG. From left to right: stripped Hb, Hb + CO_2 , Hb + BPG, Hb + BPG + CO_2 , and whole blood.

been implicated as the major players in the Bohr effect. (The pK_a of a free amino terminus in a protein is about 8.0, but the pK_a of a protein histidine imidazole is around 6.5.) Neighboring carboxylate groups of Asp $\beta 94$ residues help stabilize the protonated state of the His $\beta 146$ imidazoles that occur in deoxyhemoglobin. However, when Hb binds O_2 , changes in the conformation of β -chains upon Hb oxygenation move the negative Asp function away, and dissociation of the imidazole protons is favored.

15.6m CO_2 Also Promotes the Dissociation of O_2 from Hemoglobin

Carbon dioxide has an effect on O_2 binding by Hb that is similar to that of H^+ , partly because it produces H^+ when it dissolves in the blood:

The enzyme *carbonic anhydrase* promotes the hydration of CO_2 . Many of the protons formed upon ionization of carbonic acid are picked up by Hb as O_2 dissociates. The bicarbonate ions are transported with the blood back to the lungs. When Hb becomes oxygenated again in the lungs, H^+ is released and reacts with HCO_3^- to re-form H_2CO_3 , from which CO_2 is liberated. The CO_2 is then exhaled as a gas.

In addition, some CO_2 is directly transported by hemoglobin in the form of *carbamate* ($-\text{NHCOO}^-$). Free α -amino groups of Hb react with CO_2 reversibly:

This reaction is driven to the right in tissues by the high CO_2 concentration; the equilibrium shifts the other way in the lungs where $[\text{CO}_2]$ is low. Thus, carbamylation of the N-termini converts them to anionic functions, which then form salt links with the cationic side chains of Arg $\alpha 141$ that stabilize the deoxy or T state of hemoglobin.

In addition to CO_2 , Cl^- and BPG also bind better to deoxyhemoglobin than to oxyhemoglobin, causing a shift in equilibrium in favor of O_2 release. These various effects are demonstrated by the shift in the oxygen saturation curves for Hb in the presence of one or more of these substances (Figure 15.28). Note that the O_2 -binding curve for Hb + BPG + CO_2 fits that of whole blood very well.

15.6n 2,3-Bisphosphoglycerate Is an Important Allosteric Effector for Hemoglobin

The binding of 2,3-bisphosphoglycerate (BPG) to Hb promotes the release of O_2 (Figure 15.28). Erythrocytes (red blood cells) normally contain about 4.5 mM BPG, a concentration equivalent to that of tetrameric hemoglobin molecules. Interestingly, this equivalence is maintained in the Hb-BPG binding stoichiometry because the tetrameric Hb molecule has but one binding site for BPG. This site is situated within the central cavity formed by the association of the four subunits. The strongly negative BPG molecule (Figure 15.29) is electrostatically bound via interactions with the positively charged functional groups of each Lys β 82, His β 2, His β 143, and the NH_3^+ -terminal group of each β -chain. These positively charged residues are arranged to form an electrostatic pocket complementary to the conformation and charge distribution of BPG (Figure 15.30). In effect, BPG crosslinks the two β -subunits. The ionic bonds between BPG and the two β -chains aid in stabilizing the conformation of Hb in its deoxy form, thereby favoring the dissociation of oxygen. In oxyhemoglobin, this central cavity is too small for BPG to fit. Or, to put it another way, the conformational changes in the Hb molecule that accompany O_2 binding perturb the BPG-binding site so that BPG can no longer be accommodated. Thus, BPG and O_2 are mutually exclusive allosteric effectors for Hb, even though their binding sites are physically distinct.

15.6o BPG Binding to Hb Has Important Physiological Significance

The importance of the BPG effect is evident in Figure 15.28. Hemoglobin stripped of BPG is virtually saturated with O_2 at a pO_2 of only 20 torr, and it cannot release its oxygen within tissues, where the pO_2 is typically 40 torr. BPG shifts the oxygen saturation curve of Hb to the right, making Hb an O_2 delivery system eminently suited to the needs of the organism. BPG serves this vital function in humans, most primates, and a number of other mammals. However, the hemoglobins of cattle, sheep, goats, deer, and other animals have an intrinsically lower affinity for O_2 , and these Hbs are relatively unaffected by BPG.

15.6p Fetal Hemoglobin Has a Higher Affinity for O_2 Because It Has a Lower Affinity for BPG

The fetus depends on its mother for an adequate supply of oxygen, but its circulatory system is entirely independent. Gas exchange takes place across the placenta. Ideally then, fetal Hb should be able to absorb O_2 better than maternal Hb so that an effective transfer of oxygen can occur. Fetal Hb differs from adult Hb in that the β -chains are replaced by very similar, but not identical, 146-residue subunits called γ -chains (gamma chains). Fetal Hb is thus $\alpha_2\gamma_2$. Recall that BPG functions through its interaction with the β -chains. BPG binds less effectively with the γ -chains of fetal Hb (also called Hb F). (Fetal γ -chains

Figure 15.29 The structure, in ionic form, of BPG or 2,3-bisphosphoglycerate, an important allosteric effector for hemoglobin. 2,3-PG is shown in the three common structural representations used in this book.

Figure 15.30 The ionic binding of BPG to the two β -subunits of Hb. BPG lies at center of the cavity between the two β -subunits. The highlighted residues are N-terminal Val β_1 and Val β_2 (yellow), His β_1 2, His β_2 2, His β_1 143, and His β_2 143 (purple), Lys β_1 82 and Lys β_2 82 (green) (PDB id = 1B86).

Human Biochemistry

Hemoglobin and Nitric Oxide

Nitric oxide ($\text{NO} \cdot$) is a simple gaseous molecule whose many remarkable physiological functions are still being discovered. For example, $\text{NO} \cdot$ is known to act as a neurotransmitter and as a second messenger in signal transduction. Furthermore, **endothelial relaxing factor** (ERF, also known as endothelium-derived relaxing factor, or EDRF), a once-elusive hormonelike agent that acts to relax the musculature of the walls (**endothelium**) of blood vessels and lower blood pressure, has been identified as $\text{NO} \cdot$. It has long been known that $\text{NO} \cdot$ is a high-affinity ligand for Hb, binding to its heme- Fe^{2+} atom 10,000 times better than O_2 . An enigma thus arises: Why isn't $\text{NO} \cdot$ instantaneously bound by Hb within human erythrocytes and prevented from exerting its vasodilation properties?

The reason that Hb doesn't block the action of $\text{NO} \cdot$ is due to a unique interaction between Cys 93 β of Hb and $\text{NO} \cdot$ discovered by Li Jia, Celia and Joseph Bonaventura, and Jonathan Stamler at Duke University. Nitric oxide reacts with the sulfhydryl group of Cys 93 β , forming an S-nitroso derivative:

This S-nitroso group is in equilibrium with other S-nitroso compounds formed by reaction of $\text{NO} \cdot$ with small-molecule thiols such as free cysteine or glutathione (an isoglutamylcysteinylglycine tripeptide):

S-nitrosogluthathione

These small-molecule thiols serve to transfer $\text{NO} \cdot$ from erythrocytes to endothelial receptors, where it acts to relax vascular tension. $\text{NO} \cdot$ itself is a reactive free-radical compound whose biological half-life is very short (1–5 s). S-nitrosogluthathione has a half-life of several hours.

The reactions between Hb and $\text{NO} \cdot$ are complex. $\text{NO} \cdot$ forms a ligand with the heme- Fe^{2+} that is quite stable in the absence of O_2 . However, in the presence of O_2 , $\text{NO} \cdot$ is oxidized to NO_3^- and the heme- Fe^{2+} of Hb is oxidized to Fe^{3+} , forming methemoglobin. Fortunately, the interaction of Hb with $\text{NO} \cdot$ is controlled by the allosteric transition between R-state Hb (oxyHb) and T-state Hb (deoxyHb). Cys 93 β is more exposed and reactive in R-state Hb than in T-state Hb, and binding of $\text{NO} \cdot$ to Cys 93 β precludes reaction of $\text{NO} \cdot$ with heme iron. Upon release of O_2 from Hb in tissues, Hb shifts conformation from R state to T state, and binding of $\text{NO} \cdot$ at Cys 93 β is no longer favored. Consequently, $\text{NO} \cdot$ is released from Cys 93 β and transferred to small-molecule thiols for delivery to endothelial receptors, causing capillary vasodilation. This mechanism also explains the puzzling observation that free Hb produced by recombinant DNA methodology for use as a whole-blood substitute causes a transient rise of 10 to 12 mm Hg in diastolic blood pressure in experimental clinical trials. (Conventional whole-blood transfusion has no such effect.) It is now apparent that the “synthetic” Hb, which has no bound $\text{NO} \cdot$, is binding $\text{NO} \cdot$ in the blood and preventing its vasoregulatory function.

In the course of hemoglobin evolution, the only invariant amino acid residues in globin chains are His F8 (the obligatory heme ligand) and a Phe residue acting to wedge the heme into its pocket. However, in mammals and birds, Cys 93 β is also invariant, no doubt due to its vital role in $\text{NO} \cdot$ delivery.

Adapted from Jia, L., et al., 1996. S-Nitrosohaemoglobin: A dynamic activity of blood involved in vascular control. *Nature* **380**:221–226.

Figure 15.31 Comparison of the oxygen saturation curves of Hb A and Hb F under similar conditions of pH and [BPG].

have Ser instead of His at position 143 and thus lack two of the positive charges in the central BPG-binding cavity.) Figure 15.31 compares the relative affinities of adult Hb (also known as Hb A) and Hb F for O_2 under similar conditions of pH and [BPG]. Note that Hb F binds O_2 at pO_2 values where most of the oxygen has dissociated from Hb A. Much of the difference can be attributed to the diminished capacity of Hb F to bind BPG (compare Figures 15.28 and 15.31); Hb F thus has an intrinsically greater affinity for O_2 , and oxygen transfer from mother to fetus is ensured.

15.6q Sickle-Cell Disease Is Characterized by Abnormal Red Blood Cells

In 1904, a Chicago physician treated a 20-year-old Black college student complaining of headache, weakness, and dizziness. The blood of this patient revealed serious anemia—only half the normal number of red cells were present. Many of these cells were abnormally shaped; in fact, instead of the characteristic disc shape, these erythrocytes were elongated and crescentlike in form, a feature that eventually gave name to the disease. These sickle cells pass less freely through the capillaries, impairing circulation and causing tissue damage. Furthermore, these cells are more fragile and rupture more easily than normal red cells, leading to anemia.

15.6r Sickle-Cell Disease Has Been Characterized as a Molecular Disease

A single amino acid substitution in the β -chains of Hb causes sickle-cell disease. Replacement of the glutamate residue at position 6 in the β -chain by a valine residue marks the only chemical difference between Hb A and sickle-cell hemoglobin, Hb S. The amino acid residues at position $\beta 6$ lie at the surface of the hemoglobin molecule. In Hb A, the ionic R groups of the Glu residues are suited to this environment. In contrast, the aliphatic side chains of the Val residues in Hb S create hydrophobic protrusions where none existed before. To the detriment of individuals who carry this trait, a hydrophobic pocket forms in the EF corner of each β -chain of Hb when it is in the deoxy state, and this pocket nicely accommodates the Val side chain of a neighboring Hb S molecule (Figure 15.32). This interaction leads to the aggregation of Hb S molecules into long, chainlike polymeric structures. The obvious consequence is that deoxyHb S is less soluble than deoxyHb A. The concentration of hemoglobin in red blood cells is high (about 150 mg/mL), so even in normal circumstances it is on the verge of crystallization. The formation of insoluble deoxyHb S fibers distorts the red cell into the elongated sickle shape characteristic of the disease.²

²In certain regions of Africa, the sickle-cell trait is found in 20% of the people. Why does such a deleterious heritable condition persist in the population? Individuals with this trait are less susceptible to the most virulent form of malaria. The geographic distribution of malaria and the sickle-cell trait are positively correlated.

Figure 15.32 The polymerization of Hb S via the interactions between the hydrophobic Val side chains at position $\beta 6$ and the hydrophobic pockets in the EF corners of β -chains in neighboring Hb molecules. **(a)** The protruding block on Oxy S represents the Val hydrophobic protrusion. The complementary hydrophobic pocket in the EF corner of deoxy β -chains is represented by a square-shaped indentation. (This indentation is probably present in Hb A also.) Only the β_2 Val protrusions and the β_1 EF pockets are shown. (The β_1 Val protrusions and the β_2 EF pockets are not involved, although they are present.) **(b)** The polymerization of Hb S via β_2 Val₆ insertions into neighboring β_1 pockets. **(c)** Molecular graphic of an Hb S dimer of tetramers. β_2 Val residues are highlighted in blue; heme is shown in red (PDB id = 2HBS). **(d)** Molecular graphic of the Hb S filament (PDB id = 2HBS). Recall that heme is bound in the EF cleft, so heme highlights the location of the β_2 Val-binding site on β_1 subunits.

Foundational Biochemistry Things You Should Know after Reading Chapter 15.

- The availability of substrates and cofactors usually determines the rate of an enzymatic reaction.
- As the product of the reaction accumulates, the apparent rate of product formation will slow down due to the increasing rate of the reverse reaction, which is directly dependent on [P].
- Genetic regulation of enzyme synthesis and decay determines the amount of enzyme present at any moment.
- Enzymes can be regulated allosterically through reversible binding of metabolic effectors at sites other than the active site.
- Enzyme activity can also be regulated through covalent modification, the reversible attachment of chemical groups to amino acid side chains in the enzyme.
- Enzymes susceptible to reversible covalent modification are called interconvertible enzymes.
- The enzymes that catalyze reversible covalent modification are called converter enzymes, and such converter enzymes are subject to metabolic regulation.
- Zymogens are inactive precursors from which active enzymes can be generated by proteolytic cleavage.
- Isozymes are enzymes whose subunits are homologous. The different isozyme subunits have different kinetic properties.
- Allosteric enzymes catalyze committed steps in metabolic pathways.
- Many allosteric enzymes are susceptible to feedback inhibition by the end product of the metabolic pathway.
- The kinetic behavior of allosteric enzymes does not conform to the Michaelis–Menten model for enzyme kinetics.
- Substrate saturation curves for allosteric enzymes are sigmoid (S-shaped).
- Allosteric effectors interact with allosteric enzymes at binding sites distinct from the substrate-binding (active) site.
- The activity of an allosteric enzyme can be activated or inhibited, depending on the nature of the allosteric effector it binds.
- Allosteric enzymes are oligomers; each subunit in an allosteric enzyme has a substrate-binding site and an effector-binding site.
- The interaction of allosteric enzymes with their substrates or effectors alters the conformation of the subunits.
- Conformational changes in allosteric enzymes are the basis of their changing affinity for the various ligands.

- The Monod–Wyman–Changeux (MWC) model of allosteric behavior postulates that
 1. Allosteric enzymes are oligomeric.
 2. The allosteric enzyme can exist in (at least) two conformational states, called R and T.
 3. All subunits in any molecule of enzyme are in the same conformation (either all R or all T).
 4. The different conformations of the allosteric enzyme have different affinities for the various ligands.
 5. L is the equilibrium constant for the $R \rightleftharpoons T$ equilibrium defined as $L = T_0/R_0$. If L is large, and S binds only to R, substrate binding is cooperative.
 6. The concentration of ligand giving half-maximal saturation is defined as $K_{0.5}$.
- The Monod–Wyman–Changeux (MWC) model of allosteric behavior is based on linked equilibria between conformational states and ligand-binding properties of allosteric proteins.
- The Koshland–Nemethy–Filmer (KNF) model for allosteric regulation is based on ligand-induced conformational changes in allosteric proteins.
- Reversible changes in the oligomeric state of an allosteric protein can also give rise to allosteric behavior.
- Covalent modification through reversible phosphorylation is a prominent means of metabolic regulation.
- Protein kinases catalyze the ATP-dependent phosphorylation of target proteins.
- Protein kinases phosphorylate certain Ser, Thr, or Tyr-OH side chains.
- Target recognition: The specificity of protein kinases is determined by the sequence context in which the Ser, Thr, or Tyr residue is found.
- The activity of protein kinases is regulated by intrasteric control: A pseudosubstrate sequence occupies and blocks the protein kinase active site.
- Binding of metabolic regulators (or phosphorylation) leads to the dissociation of the pseudosubstrate sequence from the protein kinase active site and activation of its protein kinase function.
- Phosphorylation is not the only form of covalent modification that regulates protein function.
- Acetylation, adenylation, uridylation, ADP-ribosylation, methylation, and disulfide oxidation–reduction are other forms of covalent modification acting in metabolic regulation.
- Glycogen phosphorylase is a paradigm of allosteric regulation and covalent modification through reversible phosphorylation.
- AMP allosterically activates glycogen phosphorylase; ATP and glucose allosterically inhibit glycogen phosphorylase.
- Glycogen phosphorylase is also regulated through reversible phosphorylation of residue Ser¹⁴.
- Glycogen phosphorylase *b*, the unphosphorylated form of the enzyme, is intrinsically less active and more susceptible to allosteric regulation than glycogen phosphorylase *a*, the phosphorylated form.
- Glycogen phosphorylase behavior reveals an important theme in metabolic regulation: covalent modification overrides allosteric regulation.
- Whether glycogen phosphorylase is covalently modified is determined by an enzyme cascade initiated by signal transduction in response to hormones.
- The signal transduction/enzyme cascade culminating in glycogen phosphorylase phosphorylation and activation involves a hormone receptor, G protein, adenylyl cyclase transmembrane signaling pathway and activation of a series of protein kinases.
- The comparative biochemistry of the oxygen-binding proteins myoglobin and hemoglobin reveals insights into allostery.
- Myoglobin (Mb) is an oxygen-storage protein; hemoglobin (Hb) is an oxygen-transport protein.
- Cooperative binding of O₂ by hemoglobin has important physiological significance in oxygen delivery to tissues.
- Oxygenation markedly alters the conformation of hemoglobin's quaternary structure.
- Deoxy- and oxy-Hb represent two conformational states of the protein.
- The allosteric behavior of Hb has attributes of both the MWC and KNF models.
- H⁺ promotes the dissociation of O₂ from Hb, as does CO₂ and 2,3-bisphosphoglycerate (BPG).
- Fetal hemoglobin has a higher affinity for O₂ than adult Hb because it has a lower affinity for BPG.
- Sickle-cell anemia is a molecular disease due to a mutation in the β -globin gene that replaces the glutamate residue at position 6 with a valine residue.
- The valine residue at position 6 in the β -globin chains of HbS (sickle cell Hb) leads to the polymerization of the deoxy form of HbS into filaments that distort the shape of red blood cells.

Problems

Answers to all problems are at the end of this book. Detailed solutions are available in the *Student Solutions Manual*.

1. **General Controls Over Enzyme Activity** List six general ways in which enzyme activity is controlled.
2. **Enzyme Induction and Repression** Describe how induction and repression can affect metabolic activity.
3. **Proteases as Zymogens** The digestive proteases are made inside pancreatic cells as inactive precursors, so-called zymogens. Why is it necessary to make these proteases as inactive precursors?
4. **Allosteric Regulation of a Pathway** Consider the sequence of enzymatic reactions in the pathway shown in the figure. Why does it make biochemical sense that enzyme 1 would be allosterically regulated rather than enzyme 5?

$$\text{enz 1} \quad \text{enz 2} \quad \text{enz 3} \quad \text{enz 4} \quad \text{enz 5}$$

$$A \longrightarrow B \longrightarrow C \longrightarrow D \longrightarrow E \longrightarrow F$$
5. **Graphical Analysis of MWC Allosteric Enzyme Kinetics** (Integrates with Chapter 13.) Draw both Lineweaver–Burk plots and Hanes–Woelf plots for an MWC allosteric enzyme system, showing separate curves for the kinetic response in (a) the absence of any effectors, (b) the presence of allosteric activator A, and (c) the presence of allosteric inhibitor I.
6. **Graphical Analysis of Negative Cooperativity in KNF Allosteric Enzyme Kinetics** The KNF model for allosteric transitions includes the possibility of negative cooperativity. Draw Lineweaver–Burk and Hanes–Woelf plots for the case of negative cooperativity in substrate

binding. (As a point of reference, include a line showing the classic Michaelis–Menten response of v to $[S]$.)

7. The Quantitative Advantage of Allosteric Behavior for O₂-Transporting Heme Proteins

The equation
$$\frac{Y}{(1 - Y)} = \frac{[pO_2]^n}{P_{50}}$$

allows the calculation of Y (the fractional saturation of hemoglobin with O₂), given P_{50} and n (see the Deeper Look box: “The Oxygen-Binding Curves of Myoglobin and Hemoglobin”). Let $P_{50} = 26$ torr and $n = 2.8$. Calculate Y in the lungs, where $pO_2 = 100$ torr, and Y in the capillaries, where $pO_2 = 40$ torr. What is the efficiency of O₂ delivery under these conditions (expressed as $Y_{\text{lungs}} - Y_{\text{capillaries}}$)? Repeat the calculations, but for $n = 1$. Compare the values for $Y_{\text{lungs}} - Y_{\text{capillaries}}$ for $n = 2.8$ versus $Y_{\text{lungs}} - Y_{\text{capillaries}}$ for $n = 1$ to determine the effect of cooperative O₂ binding on oxygen delivery by hemoglobin.

8. **Predict the Effect of Caffeine Consumption on Glycogen Phosphorylase Activity** The cAMP formed by adenylyl cyclase (Figure 15.19) does not persist because 5'-phosphodiesterase activity prevalent in cells hydrolyzes cAMP to give 5'-AMP. Caffeine inhibits 5'-phosphodiesterase activity. Describe the effects on glycogen phosphorylase activity that arise as a consequence of drinking lots of caffeinated coffee.
9. **Saturation of Hemoglobin with Oxygen** A typical red blood cell (RBC) contains about 270,000,000 hemoglobin molecules. There are approximately 25 trillion RBCs in the human circulatory system. What volume of O₂ (in L) is needed to fully saturate these RBCs? (Assume that temperature = 37°C; $P = 100$ torr and $R = 62.36367$ L torr/K mole.)
10. **Structure of cAMP** Consider the chemical structure of cAMP (Figure 15.19). Is it biochemically possible to synthesize cGMP, cCMP, and cUMP?
11. **Predict the O₂-Binding Properties of Stored Blood Whose Hemoglobin Is BPG-Depleted** If no precautions are taken, blood that has been stored for some time becomes depleted in 2,3-BPG. What happens if such blood is used in a transfusion?
12. **Estimate the Quantitative Effects of Allosteric Regulators on Glycogen Phosphorylase Activity** Enzymes have evolved such that their K_m values (or $K_{0.5}$ values) for substrate(s) are roughly equal to the in vivo concentration(s) of the substrate(s). Assume that glycogen phosphorylase is assayed at $[P_i] \approx K_{0.5}$ in the absence and presence of AMP or ATP. Estimate from Figure 15.15 the relative glycogen phosphorylase activity when (a) neither AMP or ATP is present, (b) AMP is present, and (c) ATP is present. (*Hint:* Use a ruler to get relative values for the velocity v at the appropriate midpoints of the saturation curves.)
13. **cAMP and Phosphodiesterase** Phosphodiesterase inactivates cAMP. Would inhibitors of phosphodiesterase promote or inhibit the hydrolysis of glycogen?
14. **Describe the Effects on cAMP and Glycogen Levels in Cells Exposed to Cholera Toxin** Cholera toxin is an enzyme that covalently modifies the G_s-subunit of G proteins. (Cholera toxin catalyzes the transfer of ADP-ribose from NAD⁺ to an arginine residue in G_s, an ADP-ribosylation reaction.) Covalent modification of G_s inactivates its GTPase activity. Predict the consequences of cholera toxin on cellular cAMP and glycogen levels.
15. **cAMP, G proteins and Glycogen Storage** Adenylyl cyclase is an important enzyme, playing a central role in many signaling pathways. Explain why inhibition of adenylyl cyclase would lead to more glycogen storage in the cytosol and why inhibition of the GTPase activity of the G protein that activates adenylyl cyclase would lead to less glycogen storage.
16. **One Way Negative Cooperativity Might Make Metabolic Sense** Allosteric enzymes that sit at branch points leading to several essential products sometimes display negative cooperativity for feedback inhibition (allosteric inhibition) by one of the products. What might be the advantage of negative cooperativity instead of positive cooperativity in feedback inhibitor binding by such enzymes?
17. **Kinases and Phosphatases** Enzyme activity is regulated through phosphorylation/dephosphorylation by kinases and phosphatases (see Figure 15.1). Kinases and phosphatases are in turn regulated by their own set of kinases and phosphatases and these are regulated as well. What would be the consequence, on an energy level, if kinases and phosphatases were unregulated and constantly active?
18. **Protein Kinase Specificity Via Consensus Target Sequences and Intrasteric Control** Consult Table 15.2 and
 - a. Suggest a consensus amino acid sequence within phosphorylase kinase that makes it a target of protein kinase A (the cAMP-dependent protein kinase).
 - b. Suggest an effective amino acid sequence for a regulatory domain pseudosubstrate sequence that would exert intrasteric control on phosphorylase kinase by blocking its active site.
19. **Allosteric Regulation versus Covalent Modification** What are the relative advantages (and disadvantages) of allosteric regulation versus covalent modification?
20. **Potential Treatment of Sickle-Cell Disease by Drugs Targeted to HbS** You land a post as scientific investigator with a pharmaceutical company that would like to develop drugs to treat people with sickle-cell anemia. They want ideas from you! What molecular properties of Hb S might you suggest as potential targets of drug therapy?
21. **Nitric Oxide Is a Metabolic Regulator, But What Kind?** Under appropriate conditions, nitric oxide (NO ·) combines with Cys 93β in hemoglobin and influences its interaction with O₂. Is this interaction an example of allosteric regulation or covalent modification?
22. **Is Lactate an Allosteric Effector for Mb?** Lactate, a metabolite produced under anaerobic conditions in muscle, lowers the affinity of myoglobin for O₂. This effect is beneficial, because O₂ dissociation from Mb under anaerobic conditions will provide the muscle with oxygen. Lactate binds to Mb at a site distinct from the O₂-binding site at the heme. In light of this observation, discuss whether myoglobin should be considered an allosteric protein.
23. **Morpheesins—a Model for Allosteric Regulation Based on the Reversible Association-Dissociation of a Monomeric-Oligomeric Protein** An allosteric model based on multiple oligomeric states of a protein has been proposed by E. K. Jaffe (2005). Morpheesins: A new structural paradigm for allosteric regulation. *Trends in Biochemical Sciences* 30:490–497). This model coins the term **morpheesins** to describe the different forms of a protein that can assume more than one conformation, where each distinct conformation assembles into an oligomeric structure with a fixed number of subunits. For example, conformation A of the protein monomer forms trimers, whereas conformation B of the monomer forms tetramers. If trimers and tetramers have different kinetic properties (K_m and k_{cat} values), as in low-activity trimers and high-activity tetramers, then the morpheesin ensemble behaves like an allosterically regulated enzyme. Drawing on the traditional MWC model as an analogy, diagram a simple morpheesin model in which wedge-shaped protein monomers assemble into trimers but the alternative conformation for the monomer (a square shape) forms tetramers. Further, the substrate, S, or allosteric regulator, A, binds only to the square conformation, and its binding prevents the square from adopting the wedge conformation. Describe how your diagram yields allosteric behavior.

24. Draw Substrate Saturation Curves for the Substrates of CTP Synthetase That Show Both Positive and Negative Cooperativity

CTP synthetase catalyzes the synthesis of CTP from UTP:

The substrates UTP and ATP show positive cooperativity in their binding to the enzyme, which is an α_4 -type homotetramer. However, the other substrate, glutamine, shows negative cooperativity. Draw substrate saturation curves of the form v versus $[S]/K_{0.5}$ for each of these three substrates that illustrate these effects.

25. Draw a Model for the Conformational States of Glyceraldehyde-3-P Dehydrogenase, a Tetrameric Enzyme Displaying Negative Cooperativity Glyceraldehyde-3-phosphate dehydrogenase catalyzes the synthesis of 1,3-bisphosphoglycerate:

The enzyme is a tetramer. NAD^+ binding shows negative cooperativity. Draw a diagram of possible conformational states for this tetrameric enzyme and its response to NAD^+ binding that illustrates negative cooperativity.

26. Proteomics as a Tool to Study Metabolic Regulation Proteomics studies have revealed that protein acetylation is an important mechanism for

regulation of metabolic enzymes. Describe how proteomics might have led to this discovery.

27. Hb:O₂ affinity On the basis of the graphs shown in Figures 15.27 and 15.28 and the relationship between blood pH and respiration (Chapter 2), predict the effect of hyperventilation and hypoventilation on Hb:O₂ affinity.

28. Regulation of Glycogen Phosphorylase Figure 15.18 traces the activation of glycogen phosphorylase from hormone to phosphorylation of the *b* form of glycogen phosphorylase to the *a* form. These effects are reversible when hormone disappears. Suggest reactions by which such reversibility is achieved.

Think-Pair-Share Question

Malaria and Sickle-Cell Disease When the malarial parasite *Plasmodium falciparum* infects red blood cells (RBCs), those RBCs bearing HbS are more likely to be eliminated by the liver or spleen than those bearing normal HbA. Propose a mechanism to explain why RBCs with Hb S are more likely to be eliminated than normal RBCs. (See Sections 15.6k, 15.6p and beyond for discussions on the properties of Hb and Hb S).

Essential Question

Movement is an intrinsic property associated with all living things. Within cells, molecules undergo coordinated and organized movements, and cells themselves may move across a surface. At the tissue level, muscle contraction allows higher organisms to carry out and control crucial functions, such as peristalsis in the gut and the beating of the heart. **How can biological macromolecules, carrying out conformational changes on the molecular level, achieve these feats of movement that span the microscopic and macroscopic worlds?**

Motor proteins, also known as **molecular motors**, use chemical energy (typically ATP, GTP, or ion gradients) to orchestrate movement, transforming the energy into the mechanical energy of motion. In all cases, the energy source (for example, ATP hydrolysis) is presumed to drive and control protein conformational changes that result in sliding or walking movements of one molecule relative to another. To carry out directed movements, molecular motors must be able to associate and dissociate reversibly with a polymeric protein array, a surface or substructure in the cell. ATP hydrolysis drives the process by which the motor protein ratchets along the protein array or surface. Elucidation of these basically simple processes has been extremely challenging for biochemists, involving the application of many sophisticated chemical and physical methods in many different laboratories. This chapter describes the structures and chemical functions of molecular motor proteins and some of the experiments by which we have come to understand them.

16.1 | What Are the General Features of Molecular Motors?

All molecular motors couple an energy source to a movement via protein conformational changes. Molecular motors may be linear or rotating. Linear motors crawl or creep along a polymer lattice, whereas rotating motors consist of a rotating element

Key Questions

- 16.1 What Are the General Features of Molecular Motors?
- 16.2 What Is the Molecular Mechanism of Muscle Contraction?
- 16.3 What Are the Molecular Motors That Orchestrate the Mechanochemistry of Microtubules?
- 16.4 How Do Molecular Motors Unwind DNA?
- 16.5 How Do Bacterial Flagella Use a Proton Gradient to Drive Rotation?

(the rotor) and a stationary element (the stator), in a fashion much like a simple electrical motor.

To carry out directed movements, linear molecular motors must be able to associate and dissociate reversibly with a polymeric protein array, a surface or substructure in the cell. ATP hydrolysis (or another energy source) drives the process by which the motor protein ratchets along the protein array or surface. The linear motors we will discuss include **kinesins** and **dyneins** (which crawl along microtubules), **myosin** (which slides along actin filaments in muscle), and **DNA helicases** (which move along a DNA lattice, unwinding duplex DNA to form single-stranded DNA). Rotating motors include the flagellar motor complex, described in this chapter, and the ATP synthase involved in oxidative phosphorylation.

16.2 What Is the Molecular Mechanism of Muscle Contraction?

Muscle contraction is the result of interactions between myosin and **actin**, the two predominant muscle proteins. Thick filaments of myosin slide along thin filaments of actin to cause contraction.

16.2a Muscle Contraction Is Triggered by Ca^{2+} Release from Intracellular Stores

The long and multinucleate cells of skeletal muscle are referred to as **muscle fibers**. Skeletal muscles in higher animals consist of 100 μm -diameter fibers, some as long as the muscle itself. Each of these muscle fibers contains hundreds of **myofibrils** (Figure 16.1), each of which spans the length of the fiber and is about 1 to 2 μm in diameter. Myofibrils are linear arrays of cylindrical **sarcomeres**, the basic structural units of muscle contraction. Each myofibril is surrounded by a specialized endoplasmic

Figure 16.1 The structure of a skeletal muscle cell, showing the manner in which transverse tubules enable the sarcolemmal membrane to extend into the interior of the fiber. T-tubules and sarcoplasmic reticulum (SR) membranes are juxtaposed at structures termed triad junctions (*inset*).

Human Biochemistry

Medical Applications of Smooth Muscle Effectors

Not all vertebrate muscle is skeletal muscle. Vertebrate organisms employ **smooth muscle** for long, slow, and involuntary contractions in various organs, including large blood vessels, intestinal walls, the gums of the mouth, and in the female, the uterus. Smooth muscle contraction is triggered by Ca^{2+} -activated

phosphorylation of myosin by myosin light-chain kinase (MLCK). The action of epinephrine and related agents forms the basis of therapeutic control of smooth muscle contraction. Breathing disorders, including asthma and various allergies, can result from excessive contraction of bronchial smooth muscle tissue. Treatment with epinephrine, whether by tablets or aerosol inhalation, inhibits MLCK and relaxes bronchial muscle tissue. More specific **bronchodilators**, such as **albuterol** (see accompanying figure), act more selectively on the lungs and avoid the undesirable side effects of epinephrine on the heart. Albuterol is also used to prevent premature labor in pregnant women because of its relaxing effect on uterine smooth muscle. Conversely, **oxytocin**, and its synthetic version **Pitocin**, stimulates contraction of uterine smooth muscle. This natural secretion of the pituitary gland is often administered to induce labor.

reticulum called the **sarcoplasmic reticulum (SR)**. The SR contains high concentrations of Ca^{2+} , and the release of Ca^{2+} from the SR and its interactions within the sarcomeres trigger muscle contraction. The muscle fiber is surrounded by the **sarcolemma**, a specialized plasma membrane. Extensions of the sarcolemma, called **transverse tubules**, or **t-tubules**, reach deep into the muscle fiber, enabling the sarcolemmal membrane to be in contact with each myofibril (Figure 16.1).

Skeletal muscle contractions are initiated by nerve stimuli that act directly on the muscle. Nerve impulses produce an electrochemical signal called an action potential that spreads over the sarcolemmal membrane and into the fiber along the t-tubule network. This signal induces the release of Ca^{2+} ions from the SR. These Ca^{2+} ions bind to proteins within the muscle fibers and induce contraction.

16.2b The Molecular Structure of Skeletal Muscle Is Based on Actin and Myosin

Examination of myofibrils under the electron microscope reveals a banded or striated structure. The bands are traditionally identified by letters (Figure 16.2). Regions of high electron density, denoted **A bands**, alternate with regions of low electron density, the **I bands**. Small, dark **Z lines** lie in the middle of the I bands, marking the ends of each sarcomere. Each A band has a central region of slightly lower electron density called the **H zone**, which contains a central **M disc** (also called an **M line**). Electron micrographs of cross sections of each of these regions reveal molecular details. The H zone shows a regular, hexagonally arranged array of thick filaments of myosin (15 nm diameter), whereas the I band shows a regular, hexagonal array of thin filaments of actin, together with proteins known as **tropo****nin** and **tropo****myosin** (7 nm diameter). In the dark regions at the ends of each A band, the thin and thick filaments interdigitate, as shown in Figure 16.2. The thin and thick filaments are joined by **cross-bridges**. These cross-bridges are actually extensions of the myosin molecules, and muscle contraction is accomplished by the sliding of the cross-bridges along the thin filaments, a mechanical movement driven by the free energy of ATP hydrolysis.

The Composition and Structure of Thin Filaments Actin, the principal component of thin filaments, is found in substantial amounts in most eukaryotic cells. At low ionic strength, actin exists as a 42 kDa globular protein, called **G-actin** (Figure 16.3). Under physiological conditions (higher ionic strength), G-actin polymerizes to form

Figure 16.3 The three-dimensional structure of an actin monomer from skeletal muscle. This view shows the two domains (*left* and *right*) of actin (PDB id = 1J6Z).

Figure 16.2 Electron micrograph of a skeletal muscle myofibril (in longitudinal section). The length of one sarcomere is indicated, as are the A and I bands, the H zone, the M disc, and the Z lines. Cross sections from the H zone show a hexagonal array of thick filaments, whereas the I band cross section shows a hexagonal array of thin filaments.

Figure 16.4 A molecular model of an actin polymer, based on the actin monomer structure shown in Figure 16.3 (PDB id = 1A5X). Actin consists of two strands of actin polymer wrapped around each other. This image shows three monomers in each strand.

a fibrous form of actin, called **F-actin**. As shown in Figure 16.4, F-actin is a right-handed helical structure, with a helix pitch of about 72 nm per turn. The F-actin helix is the core of the thin filament, to which tropomyosin and the **troponin complex** also add. Tropomyosin winds around actin filaments and prevents myosin binding in resting muscle. When a nerve impulse arrives at the sarcolemmal membrane, Ca^{2+} ions released from the sarcoplasmic reticulum bind to the troponin complex, inducing a conformation change that allows myosin to bind to actin, initiating contraction. In nonmuscle cells, actin filaments are the highways across which a variety of cellular cargo is transported.

The Composition and Structure of Thick Filaments Myosin, the principal component of muscle thick filaments, is a large protein consisting of six polypeptides, with an aggregate molecular weight of approximately 540 kDa. As shown in Figure 16.5, the six peptides include two 230 kDa heavy chains as well as two pairs of different 20 kDa light chains, denoted **LC1** and **LC2**. The heavy chains consist of globular amino-terminal **myosin heads**, joined to long α -helical carboxy-terminal segments, the tails. These tails are intertwined to form a left-handed coiled coil approximately 2 nm in diameter and 130 to 150 nm long. Each of the heads in this dimeric structure is associated with an LC1 and an LC2. The myosin heads exhibit ATPase activity, and hydrolysis of ATP by the myosin heads drives muscle contraction. LC1 is also known as the **essential light chain**, and LC2 is designated the **regulatory light chain**. Both light chains are homologous to calmodulin and troponin C. Dissociation of LC1 from the myosin heads in vitro results in loss of the myosin ATPase activity.

Figure 16.5 Myosin structure. **(a)** A schematic drawing of a myosin hexamer, showing the two heavy chains and four light chains. The tail is a coiled coil of intertwined α -helices extending from the two globular heads. One of each of the myosin light-chain proteins, LC1 and LC2, is bound to each of the globular heads. **(b)** A ribbon diagram shows the structure of the myosin head. The head and neck domains of the heavy chain are red; the essential light chain is yellow and the regulatory light chain is blue (PDB id = 1B7T).

The myosin head consists of a globular domain where ATP is bound and hydrolyzed, and a long α -helical neck to which the light chains are bound. The most prominent feature of the globular head is the actin-binding cleft between the so-called upper and lower domains. The N-terminal domain and the upper domain together form a seven-stranded β -sheet. The ATP-binding site is partially defined by three loops: switch 1, switch 2, and the P-loop. Conformation changes driven by ATP hydrolysis cause a rotation of the converter domain (Figure 16.5) and the long-neck helix—the fundamental event in contraction.

Repeating Structural Elements Are the Secret of Myosin's Coiled Coils A number of key features of the myosin sequence are responsible for the α -helical coiled coils formed by myosin tails. Several orders of repeating structure are found in all myosin tails, including 7, 28, and 196 residue repeating units. Large stretches of the tail domain are composed of seven residue repeating segments. The first and fourth residues of these seven residue units are generally small, hydrophobic amino acids, whereas the second, third, and sixth are likely to be charged residues. The consequence of this arrangement is shown in Figure 16.6. Seven residues form two turns of an α -helix, and in the coiled coil structure of the myosin tails, the first and fourth residues face the interior contact region of the coiled coil. Residues b, c, and f (2, 3, and 6) of the seven-residue repeat face the periphery, where charged residues can interact with the water solvent. At the 28 (4×7) residue and 196 (28×7) residue levels, specialized amino acid sequence patterns promote packing of large numbers of myosin tails in offset or staggered arrays (Figure 16.7).

Figure 16.6 An axial (top-down) view of the two-stranded, α -helical coiled coil of a myosin tail. Hydrophobic residues a and d of the 7 residue repeat sequence align to form a hydrophobic core. Residues b, c, and f face the outer surface of the coiled coil and are typically ionic.

Figure 16.7 The packing of myosin molecules in a thick filament. Adjoining molecules are offset by approximately 14 nm, a distance corresponding to 98 residues of the coiled coil. The long tails of myosin molecules are anchored at the M disk, leaving a bare zone in the middle.

16.2c The Mechanism of Muscle Contraction Is Based on Sliding Filaments

When muscle fibers contract, the thick myosin filaments slide or walk along the thin actin filaments. The basic elements of the **sliding filament model** were first described in 1954 by two different research groups: Hugh Huxley and his colleague Jean Hanson, and Andrew Huxley and his colleague Ralph Niedergerke. Several key discoveries paved the way for this model. Electron microscopic studies of muscle revealed that sarcomeres decreased in length during contraction and that this decrease was due to decreases in the width of both the I band and the H zone (Figure 16.8). At the same time, the width of the A band (which is the length of the thick filaments) and the distance from the Z discs to the nearby H zone (that is, the length of the thin filaments) did not change. These observations made it clear that the lengths of both the thin and thick filaments were constant during contraction. This conclusion was consistent with a sliding filament model.

The Sliding Filament Model The shortening of a sarcomere (Figure 16.8) involves sliding motions in opposing directions at the two ends of a myosin thick filament. Net sliding motions in a specific direction occur because the thin and thick filaments both have **directional character**. Actin filaments always extend outward from the Z lines in a uniform manner. The myosin thick filaments also assemble in a directional manner.

Careers in Chemistry

Dr. Enrique M. De La Cruz

Dr. Enrique M. De La Cruz is a Professor and Chair of Molecular Biophysics and Biochemistry at Yale University as well as the Head of Branford College where he works alongside his wife, Leslie Carmin. He received a B.S. in Biology and Chemistry at Rutgers University-Newark School of Arts and Sciences before earning his Ph.D. in Biochemistry, Cell and Molecular Biology from Johns Hopkins University School of Medicine. He

received postdoctoral training at the University of Pennsylvania.

Dr. De La Cruz and his lab integrate kinetic and thermodynamic analyses of catalytic pathways with computational modeling to help develop and test predictive models of biopolymer fragmentation, work output by motor proteins, and enzyme function and adaptation.

When asked how biochemistry shapes his daily life, Dr. De La Cruz joked, “It is in all we do!”

Figure 16.8 The sliding filament model of skeletal muscle contraction. The decrease in sarcomere length is due to decreases in the width of the I band and H zone, with no change in the width of the A band. These observations mean that the lengths of both the thick and thin filaments do not change during contraction. Rather, the thick and thin filaments slide along one another.

A Deeper Look

The P-Loop NTPases—Energy to Run the Motors

Energy obtained from hydrolysis of nucleoside triphosphates (NTPs) is fundamental to a myriad of biological processes, and indeed to life itself. The **P-loop NTPases** are an abundant class of enzymes that harness the energy of NTPs and direct it to a vast array of critical cellular functions, including molecular motors. Genomic analysis reveals that 10–18% of prokaryotic and eukaryotic genes contain P-loop NTP domains!

P-loop NTPases all contain a polypeptide loop with the sequence GxxxxGK(S/T) or GxxGK(S/T) between a β -strand and an α -helix. This sequence, the so-called **P-loop**, also known as the **Walker A motif**, coordinates the triphosphate chain of the NTP to be cleaved. The P-loop, and a second, more variable region called the **Walker B motif** ($\Psi\Psi\Psi\Psi$ [D/E], where Ψ is a hydrophobic residue), provide the binding interactions with the nucleoside triphosphate (typically ATP or GTP). The P-loop NTPases share a common $\alpha\beta\alpha$ core, consisting of a parallel β -sheet sandwiched between two sets of α -helices.

The essential features of NTP binding and hydrolysis are represented in the F_1F_0 -ATP synthase, which binds ADP and P_i and synthesizes ATP at the interface between two subunits. The ATP binding site consists of Walker A (P-loop) and Walker B motifs from the β subunit and an **arginine finger** that extends from the adjacent α subunit (see figure).

Here ADP and AlF_4^- bound in the NTP site mimic the pentavalent transition state for ATP hydrolysis, with Al in place of the γ -phosphorus of ATP and the F atoms in place of oxygens.

The mitochondrial F_1F_0 -ATP synthase is a P-loop NTPase (PDB id = 1H8E). The ATP binding site includes the α -helix, Walker A motif (P-loop), and β -sheet shown here from the β -subunit and an arginine finger (Arg373, yellow) from the α -subunit. ADP is shown in salmon, Mg in purple, and AlF_4^- in blue.

The binding and hydrolysis of NTP between adjacent subunits is a common behavior of many P-loop NTPases, as we will see with the helicases described later in this chapter.

The polarity of myosin thick filaments reverses at the M disc, which means that actin filaments on either side of the M disc are pulled toward the M disc during contraction by the sliding of the myosin heads, causing net shortening of the sarcomere.

ATP Decreases Myosin's Affinity for Actin The molecular events of contraction are powered by the ATPase activity of myosin. Much of our present understanding of this reaction and its dependence on actin can be traced to several key discoveries by Albert Szent-Györgyi at the University of Szeged in Hungary in the early 1940s.

In a series of elegant and insightful experiments, Szent-Györgyi showed the following:

- Solution viscosity is increased dramatically when solutions of myosin and actin are mixed. Increased viscosity is a manifestation of the formation of an *actomyosin complex*.
- The viscosity of an actomyosin solution is lowered by the addition of ATP, indicating that ATP decreases myosin's affinity for actin.
- Myosin ATPase activity is increased substantially by actin. (For this reason, Szent-Györgyi gave the name *actin* to the thin filament protein.) The ATPase turnover number of pure myosin is 0.05/s, but when actin is added, the turnover number increases to about 10/s, a number more like that of intact muscle fibers.

Szent-Györgyi's experiments demonstrated that ATP hydrolysis and the association and dissociation of actin and myosin are coupled. It is this coupling that enables ATP hydrolysis to power muscle contraction.

The Coupling Mechanism: ATP Hydrolysis Drives Conformation Changes in the Myosin Heads The only remaining piece of the puzzle is how the close coupling of actin-myosin binding and ATP hydrolysis result in the shortening of myofibrils. Put another way, how are ATP hydrolysis and the sliding filament model connected? The answer to this puzzle is shown in Figure 16.9. The free energy of ATP hydrolysis is translated

Figure 16.9 The mechanism of skeletal muscle contraction. **(a)** A scheme for the contraction cycle. ATP binding to the myosin head dissociates the strongly bound actomyosin rigor complex. During the recovery step, which occurs with ATP bound, the myosin head can move freely up and down. ATP hydrolysis occurs only in the up state. Binding to actin occurs with ATP hydrolysis. The power stroke is accompanied by dissociation of ADP and P_i and results in net movement of the myosin head along the actin filament. **(b)** Structures representing the four states depicted in part (a). (Adapted from Malnasi-Csizmadia, A., and Kovacs, M., 2010. Emerging complex pathways of the actomyosin powerstroke. *Trends in Biochemical Sciences* 35:684–690; and Sweeney, H. L., and Houdusse, A., 2010. Structural and functional insights into the myosin motor mechanism. *Annual Review of Biophysics* 39:539–557.)

into conformation changes in the myosin head, so dissociation of myosin and actin, hydrolysis of ATP, and rebinding of myosin and actin occur with stepwise movement of the myosin head along the actin filament. The conformation changes in the myosin head are driven by the binding and hydrolysis of ATP.

As shown in the cycle in Figure 16.9, the myosin heads are mainly dissociated from the actin filaments in resting muscle. When the signal to contract is presented (see following discussion), the myosin heads move out from the thick filaments to bind to actin on the thin filaments. Actin binding closes the cleft in the myosin head, which causes a twist in the large β -sheet. The twist causes the P-loop to open, moving away from the bound ADP and P_i . The β -sheet twist also straightens the kink in the relay helix. The power stroke occurs almost immediately, accompanied by dissociation of P_i and then ADP. The power stroke consists of a 60° rotation of the converter domain and the long α -helical neck into the down position relative to the myosin head (Figure 16.9)—a movement that results in a $100 \text{ \AA}$ movement of the end of the neck in the direction of contraction.

The end of the power stroke is termed the **rigor-like** state because without access to additional ATP, the actin–myosin pair would be locked together, unable to dissociate. However, binding another ATP causes dissociation of myosin from actin, as first noticed by Szent-Györgyi.

The conformational changes occurring in this cycle are the secret of the energy coupling that allows ATP binding and hydrolysis to drive muscle contraction.

16.3 | What Are the Molecular Motors That Orchestrate the Mechanochemistry of Microtubules?

Most eukaryotic cells contain elaborate networks of protein fibers collectively termed the **cytoskeleton**. The cytoskeleton is a dynamic, three-dimensional structure (Figure 16.10) that fills the cytoplasm and functions to:

- Establish cell shape
- Provide mechanical strength
- Facilitate cell movement
- Support intracellular transport of organelles and other cellular cargo
- Guide chromosome separation during mitosis and meiosis

Molecular motors move along the fibers of the cytoskeleton to facilitate these functions.

Figure 16.10 The cytoskeleton of eukaryotic cells. (a) Micrograph of the cytoskeleton of a eukaryotic cell (microtubules are green; nucleus is blue); (b) schematic drawing of elements of the cytoskeleton.

16.3a Filaments of the Cytoskeleton Are Highways That Move Cellular Cargo

Three types of fibers comprise the cytoskeleton: microfilaments of actin (with a diameter of 3 to 6 nm), microtubules made from tubulin (20 to 25 nm diameter), and intermediate filaments formed from a variety of proteins (about 10 nm diameter). All of these have dynamic properties that facilitate the movement of organelles and other molecular cargo through the cell.

Intermediate filaments provide a supporting network that allows cells to resist mechanical stress and deformation. Intermediate filaments are dynamic, and short filament segments can be transported across cells by motor proteins riding on microfilaments and microtubules. Polymeric actin microfilaments serve at least two functions in cells: They form networks just beneath the plasma membrane that link transmembrane proteins to cytoplasmic proteins, and they provide transcellular tracks on which organelles can be transported by myosin-like proteins. Microtubules are the best understood components of the cytoskeleton, and they are the focus of this section.

Microtubules are hollow, cylindrical structures, approximately 30 nm in diameter, formed from **tubulin**, a dimeric protein composed of two similar 55 kDa subunits known as α -tubulin and β -tubulin. Eva Nogales, Sharon Wolf, and Kenneth Downing determined the structure of the bovine tubulin $\alpha\beta$ -dimer to 3.7 Å resolution (Figure 16.11a). Tubulin dimers polymerize as shown in Figure 16.11b to form microtubules, which are essentially helical structures, with 13 tubulin monomer residues per turn. Microtubules grown *in vitro* are dynamic structures that are constantly being assembled and disassembled. Because all tubulin dimers in a microtubule are oriented similarly, microtubules are polar structures. The end of the microtubule at which growth occurs is the **plus end**, and the other is the **minus end**. Microtubules *in vitro* carry out a GTP-dependent process called **treadmilling**, in which tubulin dimers are added to the plus end at about the same rate at which dimers are removed from the minus end (Figure 16.12).

Although composed only of 55 kDa tubulin subunits, microtubules can grow sufficiently large to span a eukaryotic cell or to form large structures such as cilia and flagella. Inside cells, networks of microtubules play many functions, including formation

Figure 16.11 (a) The structure of the tubulin $\alpha\beta$ -heterodimer (PDB id = 1JFF). (b) Microtubules may be viewed as consisting of 13 parallel, staggered protofilaments of alternating α -tubulin and β -tubulin subunits. The sequences of the α - and β -subunits of tubulin are homologous, and the $\alpha\beta$ -tubulin dimers are quite stable if Ca^{2+} is present. The dimer is dissociated only by strong denaturing agents.

of the mitotic spindle that segregates chromosomes during cell division, the movement of organelles and various vesicular structures through the cell, and the variation and maintenance of cell shape. In most cells, microtubules are oriented with their minus ends toward the centrosome and their plus ends toward the cell periphery. This consistent orientation is important for mechanisms of intracellular transport.

The human genome includes seven genes for α -tubulin and eight for β -tubulin. The variation in amino acid sequence and chain length in these similar genes, termed isotypes, is mainly in the unstructured C-terminal tail (CTT) domain, which protrudes from the tubulin polymer, whereas the ~400-amino acid structural cores of α and β are highly conserved. Tubulin is subject to a large range of post-translational modifications (PTMs), almost all of which are confined to the CTT. These modifications regulate the function of associated motor proteins such as kinesins and dyneins. The various tubulin isotypes and PTMs govern motor velocity, processivity, and microtubule depolymerization rates, with substantial changes produced by even a single amino acid variation. Different molecular motors recognize distinctive tubulin structural patterns.

16.3b Three Classes of Motor Proteins Move Intracellular Cargo

Three principal classes of motor proteins move organelles and other cellular cargo on cytoskeletal filament highways in both eukaryotic and prokaryotic cells. In addition to the myosins, most cells contain kinesins and dyneins. Humans possess 40 genes for myosins, 45 for kinesins, and at least 14 for dyneins (Table 16.1). The large number of genes in each class reflects specialized structures required for a variety of functions. This diversity notwithstanding, these three classes of motor proteins share remarkable similarities of structure and function.

Kinesin 1, also called conventional kinesin, is a tetramer consisting of a dimer of heavy chains (110 kDa) associated with two light chains (65 kDa). The heavy chains contain an N-terminal motor domain, a long coiled-coil stalk with a central hinge, and a globular C-terminal tail domain where the light chains bind (Figure 16.13a). The motor domain binds to tubulin in microtubules, and the globular tail domain associates with the intended cellular cargo, for example, an organelle, an mRNA molecule, or an intermediate filament. In different kinesin families, the motor domain is located in different places in the sequence, depending on the function of the specific family.

A second class of cytoplasmic motor proteins is that of the dyneins. The first dyneins to be discovered were **axonemal dyneins**, which cause sliding of microtubules in cilia and flagella. **Cytoplasmic dyneins** were first identified in *Caenorhabditis elegans*, a nematode worm. Cytoplasmic dynein consists of a dimer of two heavy chains (500 kDa) with several other tightly associated light chains (Figure 16.13c). Each heavy chain contains a large motor domain (380 kDa) encompassing six AAA+ domains (see Section 16.4) arranged as a hexamer. A 10 nm stalk composed of a coiled coil projects from the head, between the fourth and the fifth AAA+ domains. The stalk is the microtubule-binding domain.

Figure 16.12 A model of the GTP-dependent treadmilling process. Both α - and β -tubulin possess two different binding sites for GTP. The polymerization of tubulin to form microtubules is driven by GTP hydrolysis in a process that is only beginning to be understood in detail.

Table 16.1 Genes for Molecular Motors

Genome	Number of Genes		
	Kinesins	Dyneins	Myosins
<i>Giardia lamblia</i> (protozoan parasite)	25	10	0
<i>Saccharomyces cerevisiae</i> (yeast)	25	1	5
<i>Drosophila melanogaster</i> (fruit fly)	25	13	13
<i>Caenorhabditis elegans</i> (roundworm)	20	2	17
<i>Arabidopsis thaliana</i> (flowering plant)	61	0	17
<i>Homo sapiens</i> (human)	45	14–16	40

Figure 16.13 Models of motor proteins. **(a)** Conventional kinesin (kinesin I); **(b)** Myosin V; **(c)** Cytoplasmic dynein. Dyneins contain several different light chains. The C-terminal tails of the dynein light chains designated LIC (for light intermediate chains) are the cargo-binding domains. Adapted from Vale, R., 2003. The molecular motor toolbox for intracellular transport. *Cell* **112**:467–480, and Schroeder, C. M., Ostrem, J. M. L., Hertz, N. T., and Vale, R. D., 2014. A Ras-like domain in the light intermediate chain bridges the dynein motor to a cargo-binding region. *eLife*. 3:e03351:1–22.

Myosin V (a third class of cytoplasmic motor protein) is a multimeric protein that consists of 16 polypeptide chains. The structure is built around a dimer of heavy chains, each of which includes head, neck, and tail domains (Figure 16.13b). The heavy chain head domain is virtually indistinguishable from the head domain of myosin II from skeletal muscle (see Figure 16.5), but the neck domain is three times longer than the myosin II neck helix and it contains six repeats of a *calmodulin-binding domain*. Myosin V is normally associated with an essential light chain (similar to that of myosin II), together with several calmodulins. Adjoining the neck is a 30 nm-long coiled-coil domain. The tail domain of myosin V also binds a light chain and is adapted to bind specific organelles and other cargoes.

16.3c Dyneins Move Organelles in a Plus-to-Minus Direction; Kinesins, in a Minus-to-Plus Direction

The mechanisms of intracellular, microtubule-based transport of organelles and vesicles were first elucidated in studies of *axons*, the long projections of neurons that extend great distances from the body of the cell. In these cells, it was found that sub-cellular organelles and vesicles could travel at surprisingly fast rates—as great as 1000 to 2000 nm/s—in either direction.

Cytosolic dyneins specifically move organelles and vesicles from the plus end of a microtubule to the minus end. Thus, dyneins move vesicles and organelles from the cell periphery toward the centrosome (or, in an axon, from the synaptic termini toward the cell

Human Biochemistry

Effectors of Microtubule Polymerization as Therapeutic Agents

Microtubules in eukaryotic cells are important for the maintenance and modulation of cell shape and the disposition of intracellular elements during the growth cycle and mitosis. The inhibition of microtubule polymerization can block many normal cellular processes. The alkaloid **colchicine** (see accompanying figure), a constituent of the swollen, underground stems of the autumn crocus (*Colchicum autumnale*) and meadow saffron, inhibits the polymerization of tubulin into microtubules. This blocks the mitotic cycle of plant and animal cells. Colchicine also inhibits cell motility and intracellular transport of vesicles and organelles (which in turn blocks secretory processes of cells). Colchicine has been used for hundreds of years to alleviate some of the acute pain of gout and rheumatism. In gout, white cell lysosomes surround and engulf small crystals of uric acid. The subsequent rupture of the lysosomes and the attendant lysis of the white cells initiate an inflammatory response that causes intense pain. The mechanism of pain alleviation by colchicine appears to involve inhibition of white cell movement in tissues. Interestingly, colchicine's ability to inhibit mitosis has given it an important role in the commercial development of new varieties of agricultural and ornamental plants. When mitosis is blocked by colchicine, the treated cells may be left with an extra set of chromosomes. Plants with extra sets of chromosomes are typically larger and more vigorous than normal plants. Flowers developed in this way may grow with double the normal number of petals, and fruits may produce much larger amounts of sugar.

Another class of alkaloids, the **vinca alkaloids** from *Vinca rosea*, the Madagascar periwinkle, can also bind to tubulin and inhibit microtubule polymerization. **Vinblastine** and **vincristine** are used as potent agents for cancer chemotherapy because of their ability to inhibit the growth of fast-growing tumor cells. Colchicine is not an effective chemotherapeutic agent, although it appears to act similarly to the vinca alkaloids in inhibiting tubulin polymerization.

The antitumor drug **taxol** was originally isolated from the bark of *Taxus brevifolia*, the Pacific yew tree. Like vinblastine and colchicine, taxol inhibits cell replication by acting on microtubules. Unlike these other antimetabolic drugs, however, taxol stimulates microtubule polymerization and stabilizes microtubules. The remarkable success of taxol in the treatment of breast and ovarian cancers stimulated research efforts to synthesize taxol directly and to identify new antimetabolic agents that, like taxol, stimulate microtubule polymerization.

The structures of vinblastine, vincristine, colchicine, and taxol.

body). Most kinesins, on the other hand, assist the movement of organelles and vesicles from the minus end to the plus end of microtubules, resulting in outward movement of organelles and vesicles (Figure 16.14). Certain unconventional kinesins move in the opposite direction, transporting cargo in the plus-to-minus direction on microtubules. These kinesins have their motor domain located at the C-terminus of the polypeptide.

16.3d Cytoskeletal Motors Are Highly Processive

The motors that move organelles and other cellular cargo on microtubules and actin filaments must be *processive*, meaning that they must make many steps along their cellular journey without letting go of their filamentous highway. Dyneins, nonskeletal myosins, and most kinesins are processive motors (Table 16.2). Motors in all these

Figure 16.14 Kinesins facilitate outward movement of organelles and vesicles. **(a)** Rapid axonal transport along microtubules permits the exchange of material between the synaptic terminal and the body of the nerve cell. **(b)** Vesicles, multivesicular bodies, and mitochondria are carried through the axon by this mechanism. (Adapted from a drawing by Ronald Vale.)

Table 16.2 Processivity of Motor Proteins					
Motor	Rate of Movement (nm/s)	Step Size (nm)	Distance Traveled Before Dissociating (nm)	Processivity (average number of steps before dissociating)	% Chance of Dissociating in One Step
Kinesin 1	600	8	800–1200	100–120	~1
Myosin V	1000	36	700–2100	20–60	~2–5
Dynein (cytoplasmic)	600	24–32	1000	30–40	~2–3

classes can carry cargo over roughly similar distances (700 to 2100 nm) before dissociating.¹ The step size of kinesin 1 is smaller than those of myosin V and cytoplasmic dynein; thus, its overall *processivity* (the average number of steps made before dissociating) is necessarily higher. Moving at rates of 600 to 1000 nm/s, these motors can carry their cargoes for a second or more before dissociating from their filaments.

¹Compare these distances with the dimensions of typical cells in Table 1.1.

16.3e ATP Binding and Hydrolysis Drive Hand-over-Hand Movement of Kinesin

Kinesin movement along microtubules is driven by the cycle of ATP binding and hydrolysis. The molecular details are similar in some ways to those of the skeletal muscle myosin–actin motor but are quite different in other ways. Kinesins, like skeletal muscle myosin, contain domains that open and close in response to ATP binding and hydrolysis. Together these domains act as a γ -phosphate sensor, which can detect the presence or absence of the γ -phosphate of an adenine nucleotide in the active site. The conformation changes between the ATP-bound and the ADP-bound states thus induce conformation changes that are propagated through a relay helix to a neck linker that rotates, in ways similar to skeletal muscle myosin (Figure 16.15). Thus, just as in skeletal myosin, small movements of the γ -phosphate sensor at the ATP site are translated into piston-like movement of a relay helix and then into rotations of the neck linker that result in motor movement.

Here the kinesin and myosin models diverge. The dimer of kinesin heavy chains translates these ATP-induced conformation changes into a hand-over-hand movement of its motor domain heads along the microtubule filament, in a movement akin to a judo expert throwing an opponent with a forward swing of the arm.

Figure 16.15 Ribbon structures of the myosin and kinesin motor domains and the conformational changes triggered by the relay helix. **(a)** The upper panels represent the motor domains of myosin and kinesin, respectively, in the ATP- or ADP-P_i-like state. Similar structural elements in the catalytic cores of the two domains are shown in blue, the relay helices are dark green, and the mechanical elements (neck linker for kinesin, lever arm domains for myosin) are yellow. The nucleotide is shown as a white space-filling model. **(b)** The similarity of the conformation changes caused by the relay helix in going from the ATP/ADP-P_i-bound state to the ADP-bound or nucleotide-free state is shown in the lower panels. In both cases, the mechanical elements of the protein shift their positions in response to relay helix motion. Note that the direction of mechanical element motion is nearly perpendicular to the relay helix motion. (Adapted from Vale, R. D., and Milligan, R. A., 2000. The way things move: Looking under the hood of molecular motor proteins. *Science* 288:88–95.)

Figure 16.16 A model for the motility cycle of kinesin. The two heads of the kinesin dimer work together to move processively along a microtubule. **Frame 1:** Each kinesin head is bound to the tubulin surface. The heads are connected to the coiled coil by “neck linker” segments (one shown in orange/yellow, and the other in red). **Frame 2:** Conformation changes in the neck linkers flip the trailing head by 160°, over and beyond the leading head and toward the next tubulin binding site. **Frame 3:** The new leading head binds to a new site on the tubulin surface (with ADP dissociation), completing an 80 Å movement of the coiled coil and the kinesin’s cargo. During this time, the trailing head hydrolyzes ATP to ADP and P_i . **Frame 4:** ATP binds to the leading head, and P_i dissociates from the trailing head, completing the cycle. (Adapted from Vale, R., and Milligan, R., 2000. The way things move: Looking under the hood of molecular motor proteins. *Science* 288:88–95.)

A model of kinesin motor movement is shown in Figure 16.16. Kinesin heads in solution (that is, not attached to a microtubule) contain tightly bound ADP. Binding of one head of a kinesin multimer to a microtubule causes dissociation of ADP from that head. ATP binds rapidly, triggering the neck linker to rotate or ratchet forward, throwing the second head forward as well and bringing it near the next binding site on the microtubule, 8 nm farther along the filament. The trailing head then hydrolyzes ATP and releases inorganic phosphate (but retains ADP), inducing its neck linker to return to its original orientation relative to the head. Exchange of ADP for ATP on the forward head begins the cycle again. The structure of the kinesin–microtubule complex (Figure 16.17) shows kinesin in intimate contact with the microtubule at the junction of the α - and β -subunits of a tubulin dimer.

16.3f Conformation Changes in a Hexameric Ring Drive the Dynein Motor

The movement of myosin motors on cytoskeletal actin filaments is presumed to be similar to the myosin–actin interaction in skeletal muscle. The dynein motor, by contrast, uses a hexameric ring of AAA+ modules and an associated coiled-coil stalk (see Figure 16.13) to transport cellular cargo via a different motor mechanism. ATP-dependent conformation changes in the ring of AAA+ modules must be translated into movements of the tip of the coiled-coil stalk along a microtubule. A proposed mechanism for dynein movement (Figure 16.18) suggests that the events of ATP binding and hydrolysis and ADP and P_i release at an AAA+ module swing a linker that joins the AAA+ domain and the dynein tail.

16.4 | How Do Molecular Motors Unwind DNA?

The ability of proteins to move in controlled ways along nucleic acid chains is important to many biological processes. For example, when DNA is to be replicated, the strands of the double helix must be unwound and separated to expose single-stranded DNA templates. Similarly, histone octamers (Figure 11.29) slide along DNA strands in chromatin remodeling, Holliday junctions move, and nucleic acids move in and out of viral capsids. The motor proteins that move directionally along nucleic acid strands and accomplish these many functions are called **translocases**. The translocases that unwind DNA or RNA duplex substrates are termed **helicases**. Thus, all helicases are translocases, but not vice versa.

Figure 16.17 In the kinesin–microtubule complex, the switch 2 helix (yellow) of kinesin (left) lies in contact with the microtubule (right) at the subunit interface of a tubulin dimer (PDB id = 2HXH).

Figure 16.18 Structure and mechanism of the dynein motor. **(a)** Molecular graphic model of dynein bound to a microtubule (courtesy of James Spudich). A mechanism for the dynein power stroke involves conformation changes in the head domain **(b)** that facilitate movement of the stalk along a microtubule **(c)**. ATP binding to the motor domain promotes dissociation of dynein from the microtubule. Hydrolysis of ATP causes a conformation change that primes the structure for a power stroke. Microtubule movement is initiated by tight binding to the tip of the stalk, which promotes a conformation change in the head ring (the power stroke). Release of ADP and P_i from the catalytic site causes tilting of the stalk at the end of the cycle. (Adapted from Oiwa, K., and Sakakibara, H., 2005. Recent progress in dynein structure and mechanism. *Current Opinion in Cell Biology* 17:98–103.)

All translocases and helicases are members of six protein superfamilies (Table 16.3 and Figure 16.19), all of them related evolutionarily to **RecA**, a DNA-binding protein (See A Deeper Look box “The P-Loop NTPases—Energy to Run the Motors” in Section 16.2). **Superfamily 1 (SF1) and superfamily 2 (SF2)** helicases are monomeric and consist of two RecA domains in a tandem repeat. SF1 and SF2 helicases participate in several diverse DNA and RNA manipulations. The other helicases (SF3–SF6), which often participate at the DNA replication fork, form hexameric rings, each monomer built from a single RecA domain. Each superfamily possesses characteristic conserved residues and sequence elements (Table 16.3), most of which are shared between several superfamilies. All members of a given superfamily move in the same direction on a DNA or RNA template (either 5′ to 3′ or 3′ to 5′). In the hexameric helicases, the ATP site consists of elements derived from adjacent monomers in the complex. The hexameric motor proteins of the SF3 and SF6 superfamilies are members of the ancient **AAA+ ATPase family**. (AAA stands for ATPases associated with various cellular activities, and the + sign refers to an expanded definition of the family characteristics.)

Translocases and helicases, like other molecular motors, require energy for their function. The energy for movement along a nucleic acid strand, as well as for separation of the strands of a duplex (DNA or RNA), is provided by hydrolysis of ATP.

Table 16.3	Helicase Superfamilies		
Superfamily	Quaternary Structure	Direction of Movement	Representative Motor
SF1A SF1B	Monomeric	A* B	Rep RecD
SF2	Monomeric	A or B	NS3
SF3	Hexameric	A	BPV E1
SF4	Hexameric	B	T7 gp4
SF5	Hexameric	B	Rho
SF6	Hexameric	A or B	FtsK MCM

Figure 16.19 Structures of translocase and helicase motors. **(a)** Translocase and helicase motors of SF1 and SF2 are monomers that consist of two RecA domains in a tandem repeat (PDB id = 1QHG). **(b)** Motor peptides of SF3 through SF6 associate to form hexamers (as shown) or dodecamers (PDB id = 1CR0).

Translocases and helicases move on nucleic acid strands at rates of a few base pairs to several thousand base pairs per second. These movements are carefully regulated by accessory proteins in nearly all cases. Translocases and helicases typically move along the DNA or RNA lattice for long distances without dissociating. This is termed *processive movement*, and helicases are said to have a high processivity. For example, the *E. coli* BCD helicase, which is involved in recombination processes, can unwind 33,000 base pairs before it dissociates from the DNA lattice. Processive movement is essential for helicases involved in DNA replication, where millions of base pairs must be replicated rapidly.

Helicases have evolved at least two structural and functional strategies for achieving high processivity. The hexameric helicases (of the SF3 through SF6 superfamilies) form ringlike structures that completely encircle at least one of the strands of a DNA duplex. The SF1 and SF2 helicases, notably *Rep helicase* from *E. coli*, are monomeric or homodimeric and move processively along the DNA helix by means of a hand-over-hand movement that is remarkably similar to that of kinesin's movement along microtubules. A key feature of hand-over-hand movement of a dimeric motor protein along a polymer, whether a microtubule or a DNA strand, is that at least one of the motor subunits must be bound to the polymer at any moment.

16.4a Negative Cooperativity Facilitates Hand-over-Hand Movement

How does hand-over-hand movement of a motor protein along a polymer occur? Clues have come from the structures of Rep helicase and its complexes with DNA. The Rep helicase from *E. coli* is a 76 kDa protein that is monomeric in the absence of DNA. Binding of Rep helicase to either single-stranded or double-stranded DNA induces dimerization, and the Rep dimer is the active species in unwinding DNA. Each subunit of the Rep dimer can bind either single-stranded (ss) or double-stranded (ds) DNA. However, the binding of Rep dimer subunits to DNA is negatively cooperative. Once the first Rep subunit is bound, the affinity of DNA for the second subunit is at least 10,000 times weaker than that for the first! This negative cooperativity provides an obvious advantage for hand-over-hand walking. When one hand has bound the polymer substrate, the other hand releases. A conformation change could then move the unbound hand one step farther along the polymer where it can bind again.

But what would provide the energy for such a conformation change? ATP hydrolysis is the driving force for Rep helicase movement along DNA, and the negative cooperativity of Rep binding to DNA is regulated by nucleotide binding. In the absence of nucleotide, a Rep dimer is favored, in which only one subunit is bound to ssDNA. In Figure 16.20a, this state is represented as P_2S [a Rep dimer (P_2) bound to ssDNA (S)]. Binding ATP analogs induces formation of a complex of the Rep dimer with both ssDNA and dsDNA, one to each Rep subunit (shown as P_2SD in Figure 16.20a). In their model, unwinding of the dsDNA and ATP hydrolysis occur at this point, leaving a P_2S_2 state in which both Rep subunits are bound to ssDNA. Dissociation of ADP and P_i leave the P_2S state again (Figure 16.20a).

Work by Lohman and his colleagues has shown that coupling of ATP hydrolysis and hand-over-hand movement of Rep over the DNA involves the existence of the Rep dimer in an asymmetric state. A crystal structure of the Rep dimer in complex with ssDNA and ADP shows that the two Rep monomers are in different conformations (Figure 16.20b). The two conformations differ by a 130° rotation about a hinge region between two subdomains within the monomer subunit. The hand-over-hand walking of the Rep dimer along the DNA surface may involve alternation of each subunit between these two conformations, with coordination of the movements by nucleotide binding and hydrolysis.

16.4b Papillomavirus E1 Helicase Moves along DNA as on a Spiral Staircase
